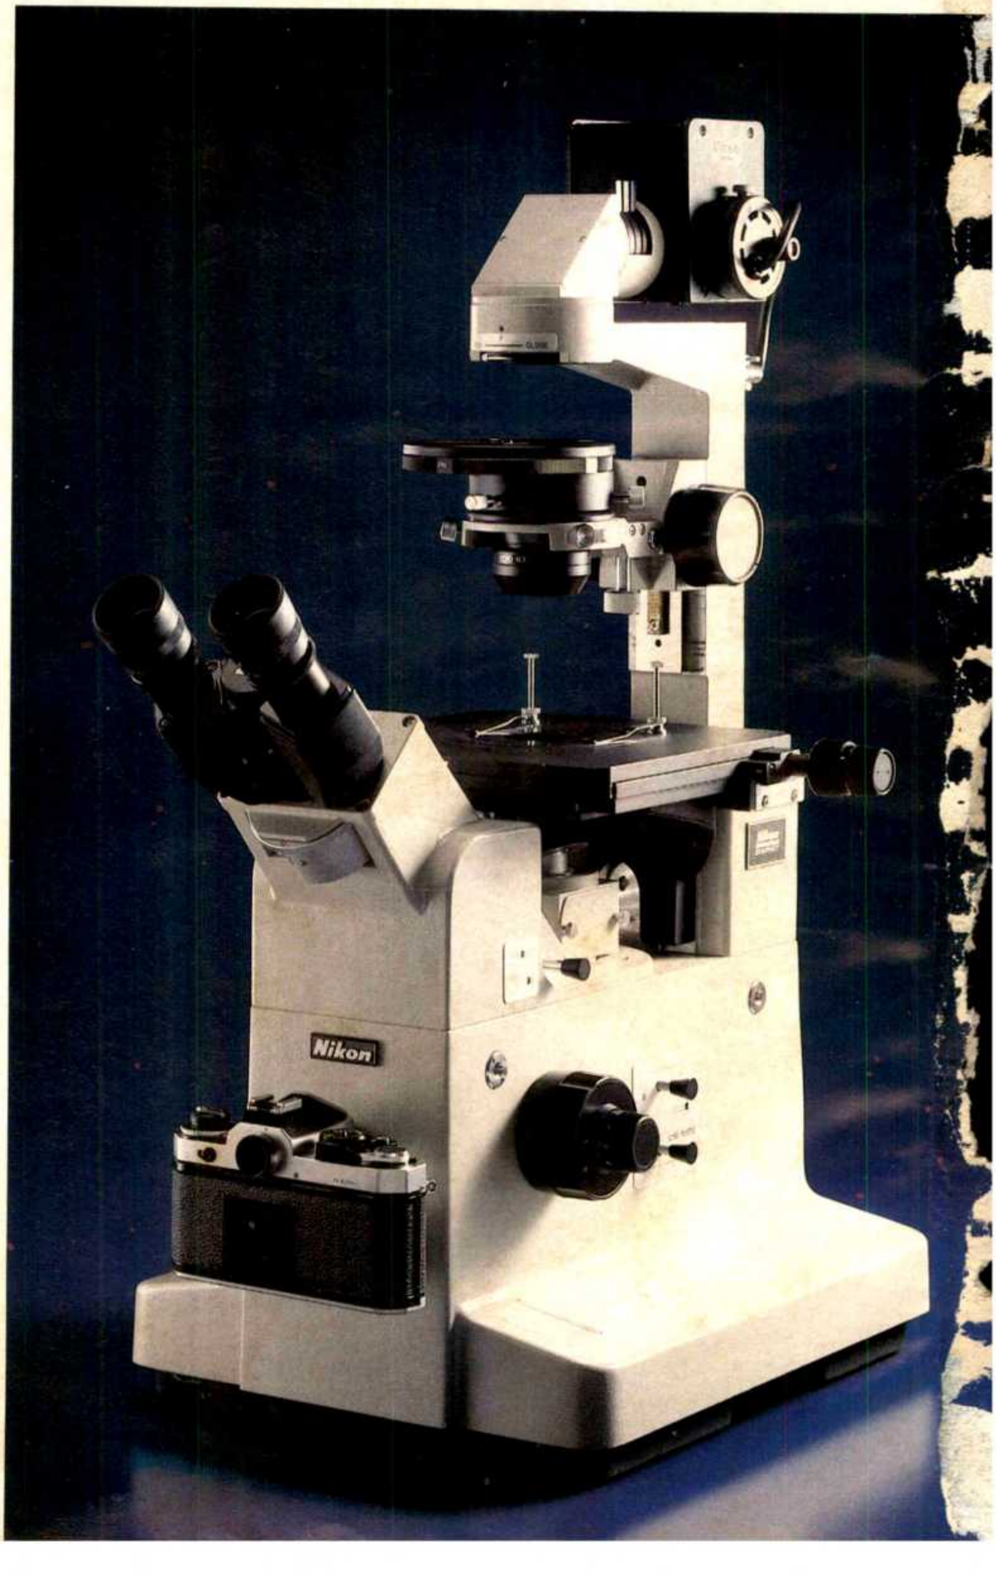
KON VISIONS

THE NIKON DIAPHOT: THE NEW INVERTED MICROSCOPE THAT'S IDEAL FOR TISSUE CULTURE RESEARCH.

CF Achromat for Phase Contrast 20XC Hell cell



When it comes to precision microscopy for tissue culture research, the Nikon Diaphot has all these advantages and more:

OPTICAL EXCELLENCE
Nikon's superb chromatic aberration-free objectives, coupled with innovative design that provides the shortest possible optical path between specimen and eye-piece, ensure sharp, high-contrast images.

EASE OF USE
The built-in turret assembly contains a focusable Bertrand lens for phase centering, and a dark slide to prevent light from entering during photography. Focusing is roller-bearing smooth, too, and the large, durable base helps keep the stage vibration-free.

PHOTOGRAPHIC CAPABILITY
Two camera ports are built in—one for 35mm photography, the other for 4 × 5 photography, CCTV, and cinemicrography.

ACCESSORIES
These include an incubator for the stage area, a reflected-light fluorescence system, even a Nomarski differential interference contrast system.

The Diaphot. You owe it to yourself to have the best.

Extend *your* vision. Write:

Inelastic neutron scattering analysis of hexokinase dynamics and its modification on binding of glucose — B Jacrot, S Cusack, A J Dianoux & D M Engelman 84

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

Spiders

E.O. Wilson: Let me remind you that people everywhere, a large percent of the population, at a very early age have already developed a deep horror at the sight of snakes or spiders with nothing more than gentle nudging from their parents, if that. Yet, in spite of the fact that parents constantly reinforce their children against going near electric sockets, automobiles, knives and the like, phobias against such objects rarely develop.

Marvin Harris: Let's go back again to the possibility that these phobias are genetically programmed – which I'm willing to grant. The overwhelming bulk of the socially conditioned response repertories of different human societies consists, by your own admission, of culturally determined rather than genetically determined traits. Then it seems to me that when one offers a cogent culturological explanation of these
has to be considered that th
offered in is

ances of human
such gigantic phenomena as the
ergence of state-organized societies or the emergence of stratified classes and castes. The enormous differences between industrial civilization and pre-industrial societies, peasant or village ways of life

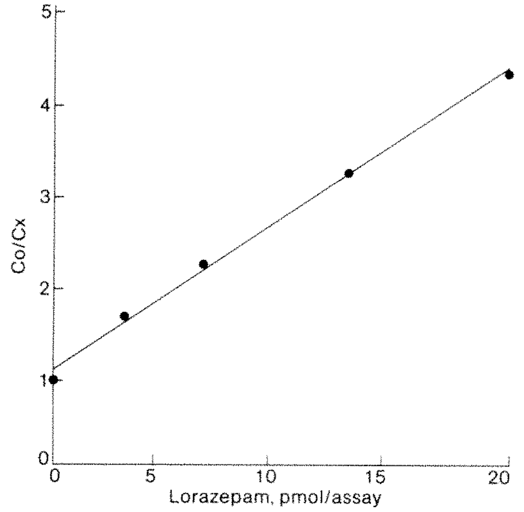
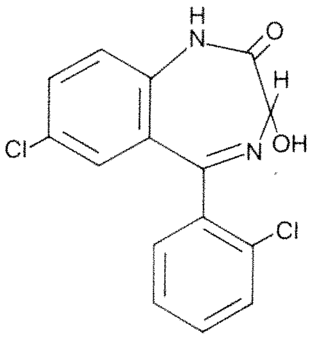
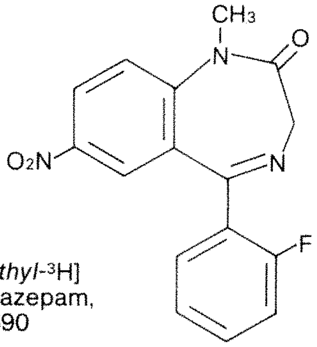
Benzodiazepine receptor preparation

Amersham's benzodiazepine receptor preparation,* N.230, provides a specific, sensitive and rapid means for the determination of benzodiazepines and their active metabolites in biological fluids.

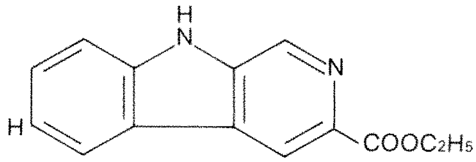




Lorazepam, N.232



[*N-methyl*-^{3}H] Flunitrazepam, TRK. 590



β-[6-^{3}H] Carboline-3-carboxylic acid, ethyl ester, TRK.664 (non-radioactive compound, N.231)

- **The receptor assay protocol is based on the competition between** [*N-methyl*-^{3}H] **flunitrazepam and biologically active benzodiazepines.**
- **The sensitivity of the assay is demonstrated by the standard curve shown above constructed using lorazepam, N.232.**
- **The specificity of the receptor preparation is similar to that of fresh membrane-bound rat brain benzodiazepine receptors.**

Please contact Amersham or your local distributor for further details.

ECPS 3000/150

50–3000 Volts, 1–150 mA,
50mW–150 Watts,
Constant power, current or voltage regulation.

For DNA sequencing, high resolution isoelectric focusing, and other high voltage applications.

NEW !
EPS 500/400

5–500 Volts, 1–400 mA,
Constant current or voltage regulation.

For SDS-PAGE, gradient gel electrophoresis, 2-D, agarose gel electrophoresis and immunoelectrophoresis.

Easy to use

Both power supplies are simple to use. Each one has a single bright LED display from which all parameters can be monitored easily and accurately, without confusion.

Safe

When working at high voltages, operator safety is of prime concern. Both power supplies incorporate inbuilt safety features which include a ground leakage circuit, and a unique load fault detector.

Volthour Integrator

Both power supplies can be connected to the Volthour Integrator VH-1. This provides you with the most accurate way to define the duration of any electrophoretic experiment.

For further information on the Pharmacia Power Supplies and the VH-1 contact your local Pharmacia representative.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

Molecular Biology & Medicine is a new bi-monthly journal, the first issue of which will appear in April 1983.

Molecular Biology & Medicine takes as its main task the provision of a meeting ground between the basic scientist and the clinician, and to build up connections between molecular biology and clinical medicine.

Recent rapid developments in biological sciences draw together many areas of biology and have made possible the study of aspects of human biology which only a few years ago would have been considered intractable. Such developments include:

- New methods of genetic analysis and for making gene products, i.e. recombinant DNA technology.
- New methods for dealing with complex tissue by the establishment in culture of clones of stem cells and differentiated cells.
- New methods for separating and analysing complex mixtures of molecules, e.g. new chromatographic methods, new specific reagents (monoclonal antibodies).
- New non invasive methods for detection of changes in molecules of biological interest *in vivo*, e.g. NMR.

Molecular Biology & Medicine will publish papers in molecular biology, cell biology, biochemistry, biophysics. Whilst strong preference will be given to work on human material, relevant research on other organisms will be considered. From the clinical side, work will be reported that offers the basic scientist opportunities in new areas for the application of modern concepts and new methods.

A key aspect of this journal is rapid publication of high quality papers, since it is important that papers in this fast moving field are published quickly. This requires bimonthly publication, from the outset.

The journal will publish original papers, meeting reports and book reviews but a particular feature will be the publication of views, reviews and previews written by specialists in basic and clinical sciences. These papers will encourage and provoke further thought on problems of mutual interest and on the feasibility of attacking such problems.

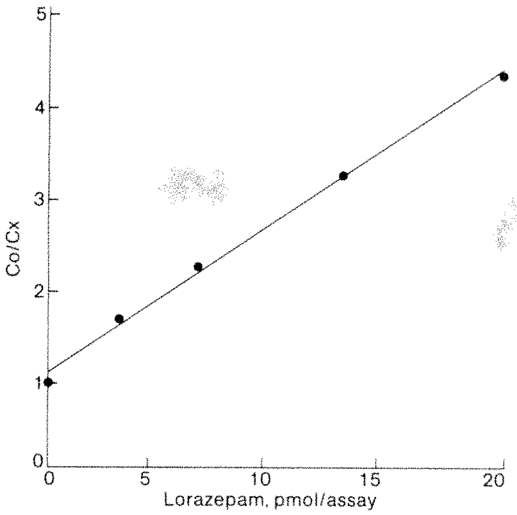
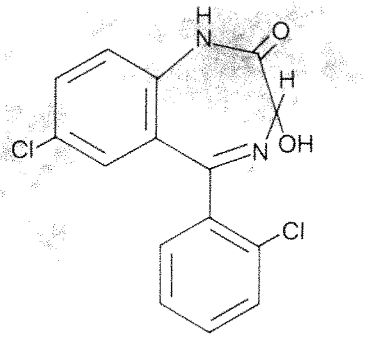
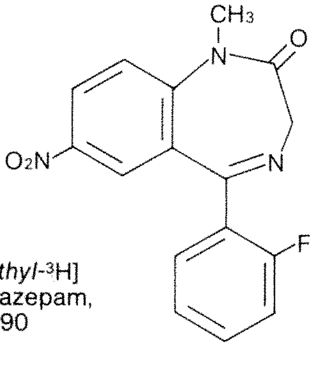
Benzodiazepine receptor preparation

Amersham's benzodiazepine receptor preparation,* N.230, provides a specific, sensitive and rapid means for the determination of benzodiazepines and their active metabolites in biological fluids.

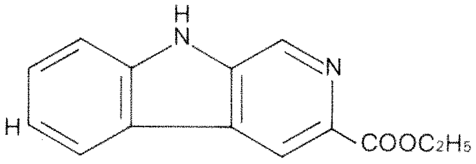




Lorazepam, N.232



[*N-methyl*-^{3}H] Flunitrazepam, TRK. 590



ß-[6-^{3}H] Carboline-3-carboxylic acid, ethyl ester, TRK.664 (non-radioactive compound, N.231)

- **The receptor assay protocol is based on the competition between [*N-methyl*-^{3}H] flunitrazepam and biologically active benzodiazepines.**
- **The sensitivity of the assay is demonstrated by the standard curve shown above constructed using lorazepam, N.232.**
- **The specificity of the receptor preparation is similar to that of fresh membrane-bound rat brain benzodiazepine receptors.**

Please contact Amersham or your local distributor for further details.

Gel Filtration

with major benefits

ULTROGEL
AcA
UNIQUE
Polyacrylamide-Agarose
Net work

HIGH RESOLUTION

ensured by regular polyacrylamide network and narrow bead size distribution.

HIGH FLOW RATE

as a result of the rigidity of the agarose moiety

HIGH REPRODUCIBILITY

extended quality controls prevent from batch to batch variations.

LONG LIFE-TIME

resulting from absence of non specific adsorption and thus easy regeneration.

EASY TO USE

beads are preswollen and allow a large choice of flow-rates.

WIDE RANGE

Gel	Fractionation range	Exclusion limit
AcA 202	1 000- 15 000	22 000
AcA 54	5 000- 70 000	90 000
AcA 44	10 000- 130 000	200 000
AcA 34	20 000- 350 000	750 000
AcA 22	100 000- 1 200 000	3 000 000
A6	25 000- 2 400 000	4 000 000
A4	55 000- 9 000 000	20 000 000
A2	120 000-25 000 000	50 000 000

The Ultrogel range includes also the Ultrogel A (agarose gels) for very high molecular weight gel filtration and affinity chromatography.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

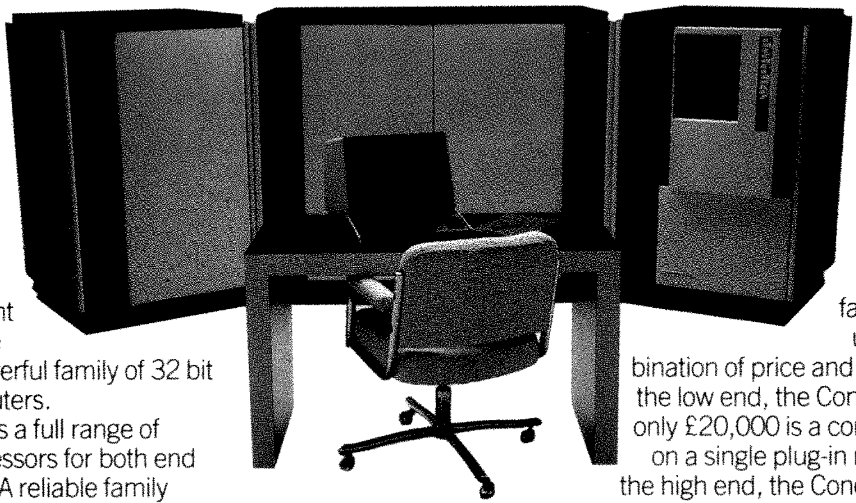
When you're buying a minicomputer, invest with confidence in the experience of GOULD S.E.L.



As a major division of the $2.2 billion international Gould Corporation, Gould SEL present Concept 32—the world's most powerful family of 32 bit super minicomputers.

Concept 32 is a full range of compatible processors for both end user and OEM's. A reliable family capable of handling any systems application.

Scientific data processing. Computational processing. Programme development. Simulation. Industrial Automation. Large process control and monitoring. Right through to data management.

To date, we have successfully installed more than 200 Concept 32 systems for customers throughout the UK. Major commercial and industrial organisations such as British Aerospace, the British National Oil Corporation, Dunlop and Rolls-Royce to name but a few.

The Concept 32 family provides an unbeatable combination of price and performance. At the low end, the Concept 32/27 from only £20,000 is a compact processor on a single plug-in module, whilst at the high end, the Concept 32/87 is the world's fastest 32 bit super minicomputer — for under £100,000 it's over 3 times faster than any other minicomputer system.

This broad range of power makes the Concept 32 family the perfect choice for your systems application.

So if you're thinking of buying a minicomputer, follow the lead of some of the biggest names in British Industry. And invest with confidence in the experience of Gould SEL.

Circle No.31 on Reader Service Card.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

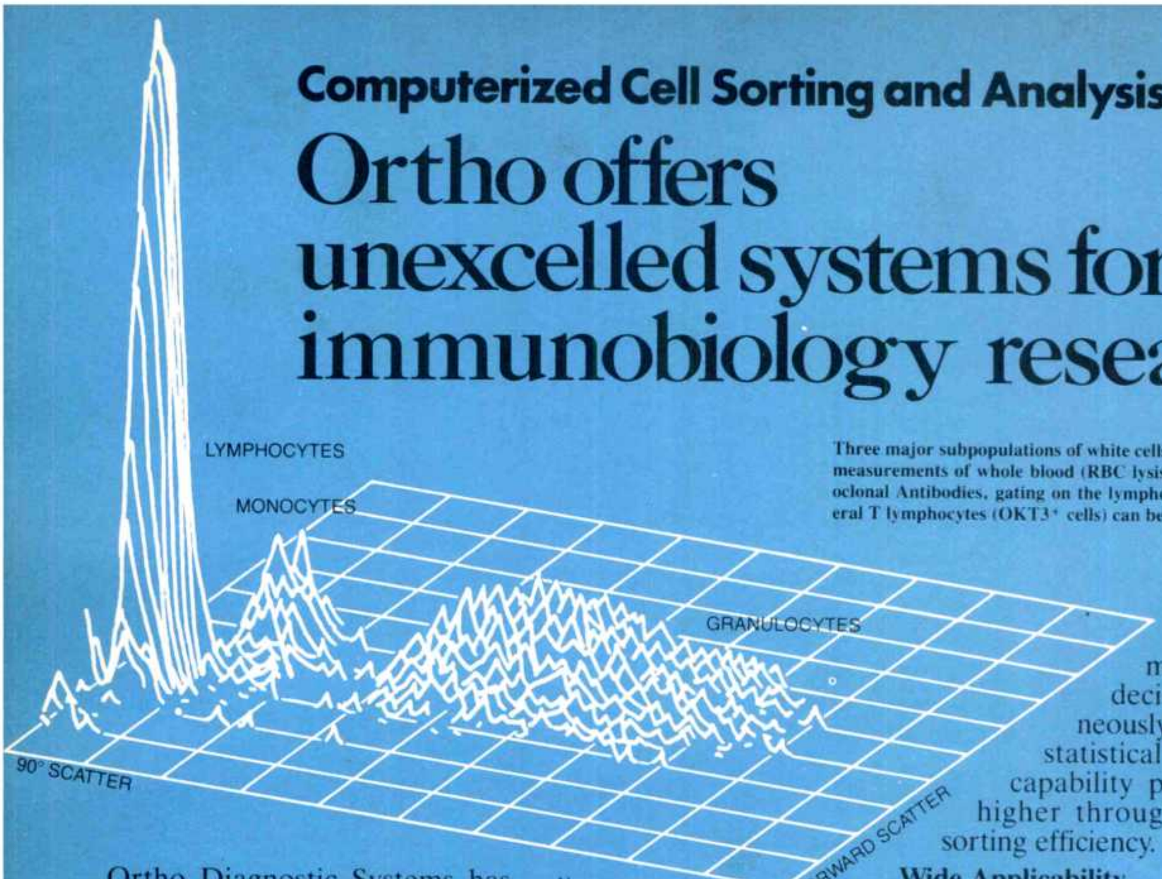
References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

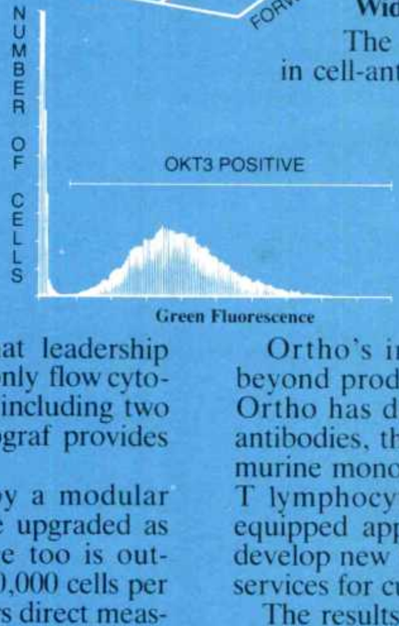
Computerized Cell Sorting and Analysis from Ortho

Ortho offers unexcelled systems for immunobiology researchers



Three major subpopulations of white cells by forward and 90° light scatter measurements of whole blood (RBC lysis only). Using Ortho-mune Monoclonal Antibodies, gating on the lymphocyte population, human peripheral T lymphocytes (OKT3⁺ cells) can be quantitated and/or sorted.

Ortho Diagnostic Systems has established a firm leadership position in cell sorting and analysis instrumentation—in fact, acceptance of Ortho systems by the scientific community has been so great that these instruments now are considered the standard of performance in the field.



Green Fluorescence

Versatile Instrumentation

The Ortho Cytofluorograf* Flow Cytometer is an example of that leadership and commitment to research. As the only flow cytometer to offer a choice of five lasers, (including two installed as standard), the Cytofluorograf provides exceptional applications flexibility.

Flexibility is enhanced further by a modular design which allows the system to be upgraded as research needs change. Performance too is outstanding with analysis rates of up to 10,000 cells per second. And only Cytofluorograf offers direct measurement of seven optical parameters including axial light loss, a valuable technique that allows the use of non-fluorescent stains.

The new 2150 Computer and software can acquire up to 16 histograms and simultaneously display any four of these, all in real-time, allowing the operator complete control over all aspects of the experiment. Because 2150 has two independent microprocessors, it can perform rapid multiparameter sort decisions while simultaneously providing complete statistical data analysis. This capability provides significantly higher throughput and increased sorting efficiency.

Wide Applicability

The system has proved extremely valuable in cell-antigen and tumor studies. It can also be employed for research into cell sizing, DNA and chromosome analysis and many aspects of cell kinetics and microbiology. The exceptional versatility of the system allows it to keep pace with the researcher's interests, never to limit them.

Total Professional Support

Ortho's interest in cellular biology extends beyond producing instrumentation. For example, Ortho has developed Ortho-mune* monoclonal antibodies, the first panel (for research use only) of murine monoclonal antibodies reactive with human T lymphocytes. The company maintains well-equipped applications and training laboratories to develop new techniques and to provide consultative services for customers.

The results of these investigations and others are published in Protocols so that other researchers may share the results. Free copies are available by contacting Ortho.

Ask about the Cytofluorograf Flow Cytometer, 2150 and the complete range of Ortho services. Contact Ortho Diagnostic Systems Inc., Research Instruments Division, 410 University Avenue, Westwood, MA 02090 (617) 329-6100.

Contents continued overleaf

Protein labelling reagents

- **Non-penetrating plasma membrane isolation reagent**[1]

TRK.696

[^3H] **IDNPAP**

Isethionyl-3 (*N*-2,4-dinitro-[3,5-^3H] phenyl) aminopropioimidate leaves the net charge on the protein unaltered. Consequently, the labelled and unlabelled proteins will have the same characteristic pattern when isolated by electrophoretic methods[2].

- **A bi-functional protein cross-linking and labelling reagent**

CFA.674

Dimethyl[1, 8-^{14}C] **suberimidate**

$CH_3O\underset{\underset{NH}{\|}}{\overset{*}{C}}(CH_2)_6\underset{\underset{NH}{\|}}{\overset{*}{C}}OCH_3.2HCl$

This reagent has many applications as a bi-functional reagent capable of cross-linking closely neighbouring proteins. A list of references is available on request.

- **A versatile and selective reducing agent**

TRK.708

Sodium cyanoboro [^3H] **hydride**

This product is useful for the labelling of proteins by the method of Jentoff *et al*[3].

- **Specific labelling reagent for guanidyl groups**

CFA.700

[7-^{14}C] **Phenylglyoxal**

Phenylglyoxal reacts specifically with the guanidyl moiety of arginine under mild conditions – 2 molecules of the reagent reacting with each arginine residue.

Please contact Amersham or your local representative for more details of these products.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

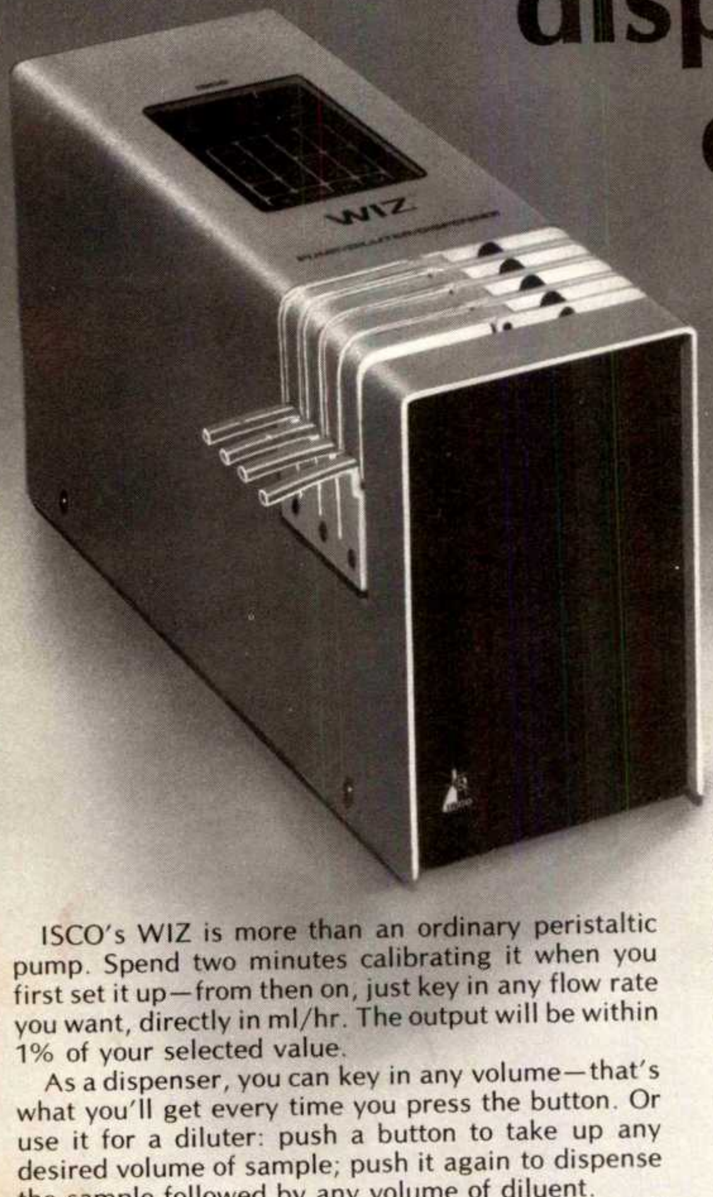
Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.*

WIZ™ is ISCO's new smartpump. It's a dispenser and diluter, too.

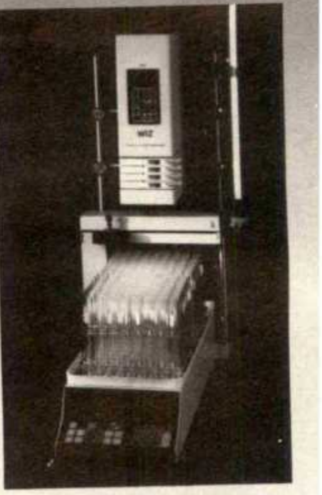


ISCO's WIZ is more than an ordinary peristaltic pump. Spend two minutes calibrating it when you first set it up—from then on, just key in any flow rate you want, directly in ml/hr. The output will be within 1% of your selected value.

As a dispenser, you can key in any volume—that's what you'll get every time you press the button. Or use it for a diluter: push a button to take up any desired volume of sample; push it again to dispense the sample followed by any volume of diluent.

WIZ has four channels, an LED display, and tubing cassettes that require no pressure adjustment and can be slipped in and out even while running. It also has design and construction quality features not found in most other pumps: microprocessor control, ball bearings, an all-metal frame and cabinet, and gear driven counter-rotation on the rollers. That means it's easy on pump tubing, reliable, and long lived.

It's a smartpump. WIZ is suitable for eluting chromatographic columns, circulating buffers and coolants in electrophoresis apparatus, and for many other laboratory applications. WIZ gives you quick system setup—you know immediately what the flow rate will be without measuring effluent or performing any calculations. You can key in any flow rate from 0.02 to 500 ml/hr/channel, combining channels to get a total of up to 2000 ml/hr. When you use WIZ with any ISCO fraction collector, you can select the fraction volume directly on the fraction collector controller. If you want 12 ml fractions, you set "12" on the fraction collector and that's what goes into each tube, regardless of selected flow rate. You can't do this with any other pump.



Wiz mounts on an ISCO FOXY fraction collector to give you the most sophisticated low pressure LC system you can put together.

It's a dispenser. Use WIZ for pipetting stock solutions, adding nutrient to culture tubes, filling ELISA plates, and for other batch assay applications. An optional dispenser handle makes the job easy.

It's a diluter. WIZ is suitable for preparing samples and standards for many analytical instruments, making serial dilutions for RIA and enzyme assays, dispensing a sample with a nutrient solution for culture assays, etc. A separating air bubble can be added after each cycle if desired.

WIZ can also be an important part of your custom automation design: use it with an ISCO ISIS AutoSampler to automate reagent addition, dilutions, and other lab processes. Send now for literature on this unique new pump, or phone toll-free: **[800] 228-4250.**

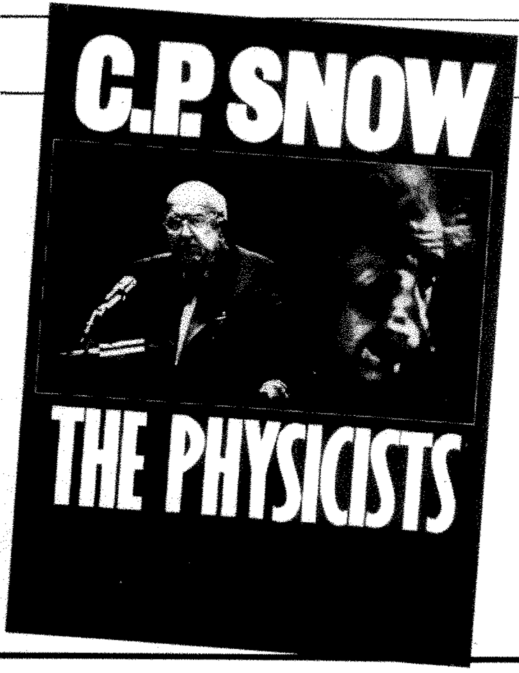
C P SNOW – THE PHYSICISTS

A GENERATION THAT CHANGED THE WORLD

'A layman can understand the complexities of a beautiful and terrible science.' *Daily Express*

'compulsive reading . . .' *Spectator*



C P Snow's last book takes the layman into the remote world of top-level science. From the 'Golden Age' of physics before World War II to the splitting of Uranium 235, the Manhattan project and, finally, Hiroshima, he brings to life the personalities and politics behind some of the cataclysmic events of this century. Brilliant and informed text illustrated with contemporary photographs throughout.

Denney
Reference Books
A DICTIONARY OF CHROMATOGRAPHY
Second Edition
R.C. Denney
Macmillan Reference Books

Essential for all Chemists

2ND EDITIONS

When you work or study in a field which is changing as fast as spectroscopy and chromatography it's not easy to keep up-to-date with all the new developments. New instruments are constantly appearing on the market and new techniques are being evolved in one of the fastest growth areas of modern science.

These dictionaries of chromatography and spectroscopy, already highly acclaimed in their previous edition, will enable you to:

* **broaden your knowledge of new products and instruments**
* **obtain rapid explanations of new terms and techniques**
* **relate your own speciality to other areas**
* **check symbols and equations quickly and efficiently**

A Dictionary of Spectroscopy covers such areas as atomic spectroscopy, emission spectroscopy, electron spin resonance, infrared and ultraviolet spectroscopy, nuclear magnetic resonance, photoelectron spectroscopy, photo luminescence, mass spectroscopy and Raman spectroscopy.

A Dictionary of Chromatography covers gas chromatography, gas liquid and gas solid chromatography, liquid chromatography, paper chromatography and thin layer chromatography.

Both dictionaries are clearly illustrated with over 50 drawings and diagrams and give numerous references for further specialised reading.

To order, just fill in this form and send it today.

OUT OF THE WORLD OF PURE SCIENCE INTO THE MAINSTREAM OF INDUSTRIAL RESEARCH AND ENGINEERING...

A communications tool of the highest quality and authority. . . BIO/TECHNOLOGY is written specifically for the rapidly emerging industrial biotechnologist — the vital and exciting new function spawned by a great wave of discovery, a surge that brings with it new, practical industrial applications. Enormous potential for progress.

With correspondents all over the world, BIO/TECHNOLOGY delivers news of the latest discoveries, new products, new methods and techniques. It enables readers to stay in touch with important work, learn about new patents and licenses, the latest government regulations that affect their work, new plant openings, new ventures, new technologies, and new instrumentation — whenever and wherever they take place.

Each issue of BIO/TECHNOLOGY brings readers original research papers by active professional scientists, engineers, and biologists. Papers that present insight into what's happening at the forefront of technology and research. For example, it presents the latest in nitrogen fixation in food crops, flow behaviour of fermentation fluids, thermodynamic aspects of microbial metabolism, the design of biological reactors, industrial waste and water treatment, fluid mixing variables, and recent energy discoveries. A special dimension is added to each paper by today's top biotechnologists, who serve as referees and discuss the work.

. . .And every issue presents the latest in genetic engineering, applied molecular biology, enzyme technologies, monoclonal antibodies and hybridomas, biomass conversion, biorecovery of minerals, recombinant DNA, fermentation science, and related energy fields.

BIO/TECHNOLOGY also reports in depth on the techniques of scaling-up to industrial production. These practical, "how to" articles are written in easily accessible language and are particularly useful to engineers who need to know more about biology — as well as to biotechnologists who want to learn more about engineering aspects of their work. BIO/TECHNOLOGY shows how "scaling-up" is being done in a diverse range of fields, from raw material extraction and reprocessing, to biomedical products, waste treatment and pollution control, food processing, pharmaceuticals, farming, new fuel and energy sources.

We take our readers behind the scenes to see how key companies are taking advantage of the new technology. Readers tour labs, see how their processes work, and learn about refinements being made in that company's products.

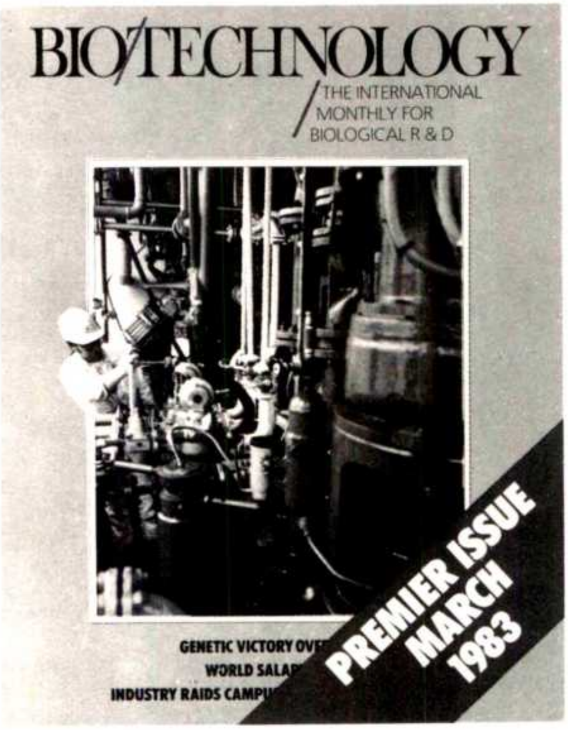
BIO/TECHNOLOGY also brings readers a wide selection of letters from active engineers and scientists working at the bench in all aspects of the field, so they stay in touch with what's happening in plants and laboratories around the world.

In addition, BIO/TECHNOLOGY features a variety of departments, including a financial page, where readers find news and analyses about corporations, venture capital firms, banking, finance, and important stock market news.

. . .And review articles, marketing news and concepts, evaluation of industry reference works, announcements of courses, book reviews, seminars and special meetings keep the readers' fingers on the pulse of important issues and industry activities.

Make BIO/TECHNOLOGY become part of **your** regular reading discipline. . . a must among the magazines you receive regularly.

As you will see, **you risk nothing by returning the coupon below and taking a look at the Premier Issue** of this unique and exciting new publication. But, in order to enjoy the first issue of the magazine, your coupon must be received promptly.



A powerful new magazine for a dynamic new field. . . from the publishers of NATURE.

BIO/TECHNOLOGY

THE INTERNATIONAL MONTHLY FOR INDUSTRIAL BIOLOGY

CALL FOR PAPERS

BIO/TECHNOLOGY offers an international forum for academic and industrial researchers to publish original research with industrial implications. Areas to be covered by this monthly periodical include but are not limited to:

- New industrial applications for existing biological structures and products.
- Modification of biological materials for use in industrial production.
- New or modified fermentation and purification systems which process biological material.
- Basic research discoveries in cell biology, biochemistry, and breeding of plants and animals which may prove to be commercially significant.

Biological research and development from the molecular level to the level of biomass conversion will be considered. DNA-transfer techniques, cell fusion, new chemical engineering methods applied to biological systems, tissue culture techniques, production and purification methods for monoclonal antibodies, and advanced chemical synthesis techniques with implications for biotechnologists are examples of areas which will be covered. Papers may have relevance to pharmaceutical, chemical, energy, agricultural, food processing, veterinary, waste management, natural products, and other industries.

BIO/TECHNOLOGY assures rapid turnover of submissions and review by internationally distinguished referees from academic life, industry, and non-profit research institutions. Color may be available for illustrations. Quality reproduction is assured.

The editors of *BIO/TECHNOLOGY* offer the same exacting standards for these applied research papers which *Nature* expects for articles on basic research subjects.

For review and possible inclusion in the Premiere Issue on March 1, 1983, please submit your manuscripts in triplicate (up to 6,000 words) or send queries as soon as possible to: Marcel Faber, Research Editor, *BIO/TECHNOLOGY*
15 East 26th Street, New York, NY 10010.

Putting a case for civil science

The British government's Advisory Board for the Research Councils has made public its advice on spending money. In the process, it has unwittingly shown how its own work could be improved.

Even British governments, notoriously shy of giving reasons for their decisions, occasionally discover that openness does not jeopardize their survival or even offend against the laughable doctrine that only ministers of the crown take decisions. That is the most obvious lesson to be drawn from the publication last week (see page 3) of this year's advice of the Advisory Board for the Research Councils to the Secretary of the State for Education and Science, Sir Keith Joseph. Hitherto, this information has been as closely (perhaps more closely) guarded than that collected by the British intelligence services, on the grounds that it would be a great embarrassment if the responsible minister decided not to follow advice given. As it happens, Sir Keith Joseph seems to be the first minister to have disagreed with the board on how the budget for civil science should be divided. Now, to his credit, he has agreed that the advice from which he in part dissents should be open to public scrutiny. One result is a better appreciation of how these important issues are decided: too casually. Another is that the minister's hand will be strengthened in the battle to come with the British Treasury about the scale of research spending in the next three years.

The advisory board itself will benefit from the need to give persuasive arguments for its advice. Among the British government's battalion of advisory committees, the board is conspicuous because its most influential members have a direct interest in whatever advice is given. Since the board was first set up, after the Rothschild inquiry in 1971, its chief function has been to divide what the government is prepared to spend on civil science among the interested parties, principally the five research councils, each of whose chief executives is a member of the board.

The fear that if dog eats dog it may itself be bitten, frequently mistaken for gentlemanly politeness, explains why over the years the distribution of the science budget has changed only in minor ways. The Science and Engineering Research Council lost a little ground in the late 1970s, when high-energy accelerators and space research became unfashionable, but that balance is now in part to be redressed. The Medical Research Council was smart enough two years ago to recapture from the Department of Health the slice of its budget transferred to the government department in 1971. Otherwise, the advisory board has operated at the margins of its dependants' budgets, trimming a little here, adding a little there. Complacency in the face of adversity seems to have been the motto.

Publicity

Even the prospect of publicity seems to have helped to jerk the board out of this self-defeating groove. Its proposal that the British Museum (Natural History) should not now build a huge new exhibition space within the shell of its splendid Victorian building is not merely an economy (£23 million plus) but a public service. The recommendation that the budget of the Agricultural Research Council should level off in cash terms (and therefore shrink in real terms) after the next financial year will cause more serious damage. This council is more trapped than others by its commitments to its own staffs working in its own research institutes. Yet the board's case for letting agriculture carry the main burden of the economies necessary to finance future spending by the Science and Engineering Research Council would be more convincing if its own statement of priorities had been more persuasive. That the board should attach importance to "developments in biology" is natural enough, even if superficially inconsistent with its recommendation about agricultural research. To count as a priority "new developments in neuroscience" is sensible enough; but this goal is surprisingly not mentioned in the statements with which the research councils bid for funds. Did one of the board's members meet a neurobiologist on a train journey, perhaps?

Fashion

The board's first public account of its way of working also raises the suspicion that it is as liable as the next person to be carried uncritically away by fashion. Thus the board blesses with £22.5 million (over three years) the Science and Engineering Research Council's wish to become the basic research sponsor in a "national programme on information technology" about to be launched by the Department of Industry, and which may cost the council £50 million over the next five years. The snag, for readers of the board's account of itself, is that there is no way of telling whether this expensive exercise is supported by an assessment of ways in which money might usefully be spent on research or merely by the enthusiasm which Mr Kenneth Baker, a minister of state at the Department of Industry, has brought to his job as minister of information technology. Fashion of a different kind also accounts for the choice of "remote sensing" as another priority area of research: the chairman of the Natural Environment Research Council, Sir Hermann Bondi, is keen; meteorological observations from satellites are practically important, while oceanic observations will soon be an important source of data in oceanography; and civil servants can readily be persuaded that the objective is to find oil, or tin, or some other mineral.

Fashion seems also to have infected the board's report in its uncritical endorsement of (and collaboration with) the study of the relations between industry, universities and the research councils commissioned by the British government from the Advisory Committee on Applied Research and Development. That committee's terms of reference are hopelessly uncritical — essentially, to identify obstacles to making university research a handmaiden of British industry and to suggest how they might be removed. The committee appointed for this task appears to be aware that there are dangers as well as benefits in links between academic and industrial organizations, principally that universities may be made less able to dispense impartially their special kind of knowledge to all potential users of it. The Advisory Board for the Research Councils, custodian of basic research though it professes to be, says nothing on this point. But if the board is silent on the risks in too particular a relationship between universities and industry, who else can be expected to have influence?

These are the respects in which the board's first public report is deficient. The document also has merit. Last December, the Select Committee on Science and Technology of the House of Lords (see *Nature* **294**, 503; 1981) complained that the board had become too passive an instrument of policy, and the British government replied that the board should exert itself in throwing light on matters of public policy (see *Nature* 8 July, p.107). No doubt the flurry of activity there has been in the past few weeks in

0028-0836/82/440001-02$01.00

setting up inquiries into topics such as the relations between research councils and universities is one sign that the board has woken up. Another is an important discussion, now published, of the demographic problems presented by the maldistribution of university teachers in most disciplines, a consequence of the rapid expansion of the 1960s. As elsewhere, there are too few young people and too many who are middle-aged (see chart, p.8). Much of the redirections of science spending planned for the next few years is intended to redress this balance, and not before time. The obvious danger is that by using money intended for research to improve the condition of British universities, the research councils may be helping to break the board's rule that they should not attempt to make good the deficiencies of the dual-support system. The snag is that self-restraint in that regard requires not merely that the councils should back good people, but that they should do so only if those people are well placed to carry out research effectively. So why should not the board spell out the criteria it expects that its dependants will follow?

A more awkward question needs to be taken up (in next year's review?): are the board's dependants as efficient as they should be? In the past few years, the peer-review systems operated by most of the research councils have won widespread respect, but many of their own research establishments fall far short of what they might be. Perhaps the most conspicuous example is the Medical Research Council's National Institute for Medical Research, which has long been balkanized into "divisions" that hardly ever speak to each other and where even minor items of expenditure must be met by cheques paid from headquarters. The board now repeats the research council's promise that its institute will be "restructured", and has appointed Dr D. A. Rees to that unenviable task. But who is to say that this one institute is not just the visible tip of a much larger problem?

Old-fashioned ways of delegating financial responsibility are certainly not confined to one institute or even to one research council. And all those that depend to some extent on contracts with government departments for the conduct of applied research are necessarily caught up in a complicated set of negotiations that only occasionally leads to a change in the pattern of expenditure. Similarly, the recruitment of extra staff within the research council system is hampered by rules dictated from on high which are designed to limit the total strength of the public service, but which prevent research council establishments from earning honest money when they can. The British Prime Minister's favourite cost-cutter, Sir Derek Rayner, is thought recently to have turned his attention to the research councils. It will be best for everybody if he discovers that the present system is too much hamstrung from outside.

The most serious defect in the working of the advisory board, now revealed, is however the incompleteness of such authority as it enjoys even in the field with which it is concerned. (The case that there should be some mechanism for overseeing the whole of publicly-supported research, defence research included, is irresistible but nevertheless repeatedly denied.) The board's membership includes most of the chief scientists of government departments which are in their own right substantial sponsors of research, much of it in universities, little of it different in kind from work sponsored by the research councils. The British government has firmly rejected the argument of the House of Lords Select Committee that there should be some device for overseeing the whole of public sponsorship of research and development, partly on the grounds that the present prime minister has a personal interest in the subject. But can it make sense that government departments, from health to industry, should be caught up in a semi-judicial (but over-casual) assessment of what the research councils should be allowed to do when their own spending in similar fields is innocent of outside inquiry? The simple answer, which all bureaucrats will echo, is that what the advisory board calls the science budget is a charge on the Department of Education and Science, and that there would be departmental barriers to a more wide-ranging inquiry. But it makes no sense that such procedural matters should inhibit what good sense requires.

Vatican and the bomb

A group of scientists has given the Pope a tactless declaration on nuclear warfare.

The Pontifical Academy of Sciences is not an academy in the strict sense (its members are invited by the Vatican) but it seems well on the way to being pontifical. The statement put out at the end of September is thus a sombre warning of the dangers of nuclear war from which few will dissent, a stern proscription of steps that might trigger off such a war and an appeal to those concerned — politicians, scientists, religious leaders "and other custodians of moral principles" — to use their best influence for the avoidance of nuclear war. The statement is a remarkable document if only because of the distinction of those who have signed it — the list includes, for example, the presidents of the National Academy of Sciences of the United States (Dr Frank Press) and of the Royal Society (Sir Andrew Huxley), acting in their personal capacities. Its weakness is that the pursuit of agreement on a set of statements about nuclear war with which nobody can quarrel seems to have obscured the more immediate issues that must be dealt with.

Even the analysis of the problem of nuclear warfare in the published statement falls short in clarity of what the members of the group individually would suggest. Thus the statement says that "there appears to be a growing fatalistic acceptance that war is inevitable and that wars will be fought with nuclear weapons". Can that be so? At a time when there are more (and more hopeful) negotiations on the limitation of nuclear weapons under way than in the past three decades? Or when military authorities are seriously considering the possibility of defending Western Europe with conventional rather than nuclear weapons? It is true, of course, that political relations between East and West in Europe have deteriorated in the past year, for which reason it is all the more remarkable that the arms negotiators in Geneva are still talking to each other, however desultorily. Similarly, it does not follow, as the Pontifical Academy of Sciences suggests, that "proliferation of nuclear weapons to additional countries seriously increases the risk of nuclear war and could lead to nuclear terrorism". If anything, the argument should be turned around: as deep and apparently irreconcilable conflicts between sovereign powers become embittered (the Middle East?), the danger that one or other party will seek nuclear weapons increases. Proliferation (of which there has been mercifully little so far) is more likely to be a symptom than a cause.

The academy's recipe for action is similarly clouded. September's statement sanely asks that nations should renew their efforts to negotiate effective arms control agreements. The distinction of the participants should carry some weight, both in Geneva and in the continuing anxiety about the design of more effective measures for safeguarding the civil trade in nuclear power. But national governments are also asked "never to be the first to use nuclear weapons". Can that be seriously intended? For most of the signatories of the document must be fully aware that this is an extremely contentious issue. In Europe, the Soviet Union has repeatedly offered a "declaration of no first use", and its Western opponents have as steadfastly refused a deal. The reasons, moreover, are well understood. Either such a declaration means nothing, or it will favour that adversary in some future conflict which is weaker in conventional forces. To couple an appeal for more serious negotiations on arms control with a declaration calculated to lose the sympathy of many of those who will read the statement is tactless, to say the least.

What can be accomplished by such manifestos? There are two choices. Either a statement on some public issue can be so penetrating and original in its analysis of a problem, or so arresting in its description of it, that ordinary people will stop and think. Or it may so powerfully suggest new things to do that statesmen will be compelled by sheer logic to follow the course prescribed. This statement on nuclear warfare is, unhappily, neither one thing nor the other.

0028-0836/82/440002-01$01.00

British research cake cut painfully

First public review reveals dissenting voice

Dissent among the five research councils has for the first time marred the customary gentility of the annual recommendations by the Advisory Board for the Research Councils (ABRC) on the British science budget. In what is meant as fighting talk, the Agricultural Research Council (ARC) says it "cannot associate" itself with the proposal that its own budget should take a declining share of the funds available beginning in the financial year 1984–85.

Ironically, this row has surfaced on the first occasion when the board's advice to the Secretary of State for Education and Science (Sir Keith Joseph) has been published. Sir Alec Merrison, the board's chairman, says that the row is unprecedented. The recommendations now made are provisional in that they will have to run the gauntlet of the British government's annual expenditure review, now under way. Sir Keith Joseph, the minister, has, however, already lopped £6 million from the proposed budgets of the Social Science Research Council (SSRC), asking that this sum should instead be used for recruiting young scientists to university posts, and has quickly fallen in with the recommendation that the British Museum (Natural History) should not spend in excess of £23 million to extend its exhibition space at South Kensington.

The recommended budgets for ARC imply a constant contribution from the science budget of £46 million in each year for the three years beginning next April, implying that the council will have to make good the unknown consequences of inflation by internal economies.

This parsimony towards ARC (and to a lesser extent towards the Natural Environment Research Council (NERC)) stems from the board's view that funds within the science budget should be diverted to other better causes — an increase in real terms of the funds available to the Science and Engineering Research Council (SERC) to support initiatives in fields such as information technology and for the provision of posts for younger scientists now frozen out of the research system.

Merrison explained last week that ARC had been singled out because of the large proportion (just over a half) of its budget channelled through the agriculture ministry to support commissioned applied research and because its links with universities are weaker than those of the other research councils.

But ARC has not yet lost hope. At a recent meeting the council endorsed the formal dissent of its secretary, Dr Ralph Riley, from the ABRC recommendations, and in the next few weeks will be asking Sir Keith Joseph to take a broader view of national priorities in general and ARC's research enterprise in particular. If more funds are not found, ARC reckons that it will have to lose 300 staff over the next three years, of whom 200 will be scientists, and that in 1984–85 it will be spending £7 million out of a total budget of £107 million to meet the cost of staff pensions and severance pay.

ABRC's argument is guided by its explicit choice of the fields in which publicly supported civil science should be encouraged: biology (especially biotechnology), remote sensing, information technology, marine resources and the neurosciences. But the board also says that its cutting of the cake this year reflects the view that the retreat from big science (experimental high-energy physics, space research) begun in the 1960s has gone far enough, and its general concern for the well-being of research and researchers in universities.

Running through the board's statement is its theme-song for 1982 — that funds spent on civil science, in universities or elsewhere, should be directed with industrial needs in mind. Its report says that it has "readily agreed" to help carry out a study (jointly with the Advisory Council on Applied Research and Development) whose terms of reference apparently leave no room for consideration of the snags that such collaboration may encounter. ●

Harvard accused of impropriety

Washington

A government audit has concluded that Harvard Medical School improperly charged $1.7 million to federal research grants from 1975 to 1977 and failed to document a further $29 million charged during the same period.

The findings by the Department of Health and Human Services (HHS), which runs the National Institutes of Health and the Public Health Service, were the latest salvos in the battle that has been waged between Harvard and the government during the five-year federal investigation of Harvard's management of grants. Last year, an HHS audit of Harvard's School of Public Health found $2.1 million in improper charges by the university.

Asked whether Harvard would repay the sums in question, the university's director of auditing, Anthony Woodworth, said, "I very much doubt it". He said both audits are the subject of negotiations with HHS officials, and that they merely represent "recommendations" to the government, not orders for repayment.

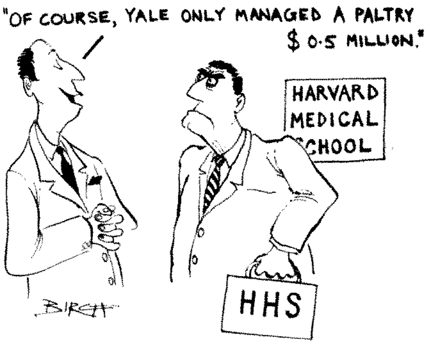
Woodworth said that an independent audit by the accounting firm of Coopers and Lybrand of Harvard's management of grants in fiscal year 1978 "gave us a clean bill of health". He suggested that HHS's release of their recent findings was a public relations stunt.

The HHS audit specifically claims that the medical school improperly transferred $1.6 million in charges from one project to another to cover cost overruns and to ensure that all available grant money was spent. The auditors said that some $3 million was charged without adequate documentation, and that the validity of $26 million that went to pay salaries could not be verified because of poor records.

Harvard appears to be trying to suggest that the dispute is one of academic freedom versus government meddling. Harvard and other universities have invoked academic freedom in resisting government efforts to require better accounting of how a faculty member divides his time between teaching and various research projects.

Harvard's attitude clearly annoys HHS. As one government official said, "What I find amazing is that we become the 'bad guys' for trying to reclaim the taxpayers' money".

Dr Delphis Goldberg, of the House Government Operations Committee panel that oversees HHS, said that the audits found problems that went deeper than the dispute over effort reporting by faculty. At the School of Public Health, he said, "there has been a substantial diversion of moneys" from specific grants to totally unrelated research projects, even projects under different principal investigators.



"OF COURSE, YALE ONLY MANAGED A PALTRY $ 0·5 MILLION."
HARVARD MEDICAL SCHOOL
HHS
BIRCH

The investigation of Harvard grew largely out of charges by Dr Phin Cohen, formerly an assistant professor of nutrition at the School of Public Health. In 1976, he accused the school of diverting funds from his NIH grant to other unrelated projects. A subsequent NIH audit confirmed his accusations — Harvard was required to return $132,000 — and recommended a full-scale audit of Harvard research grants by HHS.

NSF budget for 1983

Spending lags behind inflation

Washington

With so much of the federal budget still in doubt for the fiscal year that started in October, the National Science Foundation (NSF) considers itself fortunate that both houses of Congress have approved an appropriation bill, despite their differences, and sent a recommendation to the President which he signed before the end of of the old fiscal year.

Unfortunately, authorizing legislation — which spells out how the money should be spent — had been passed only by the House of Representatives, while because of a disagreement over who should look after NSF, two different Senate committees have worked up two different versions of NSF's authorization for fiscal year 1983. If the "lame-duck" Congress that returns later this month does not repair this situation, NSF may have to operate during the remainder of the fiscal year without detailed guidance — as it did last year.

The final amount appropriated was $1,092 million, a little more than the President's request of $1,078 million, but still close to the levels of the previous two years of $1,003 and $1,036 million respectively. With inflation, this means a net decrease.

The bulk of the money, $1,060 million, will go to NSF's research and related activities. This includes $14 million in funds taken out of other programmes which NSF can spend at its discretion.

Pre-college science education programmes, which the Administration tried to "zero" (a common verb in budget director David Stockman's vocabulary) survived with $15 million. The total NSF science education budget will be $30 million, the other $15 million going to education fellowships requested by the Administration. The House of Representatives Appropriations Committee, more sensitive to the national "crisis" in science teaching, wanted $25 million spent on pre-college education, and the Senate put in none: so they compromised.

The behavioural and social sciences were less successful in their attempts to resist Administration cutbacks. In 1982 the Administration tried to cut funds for these fields, but the social scientists fought back in Congress, and some of the money was restored. This year, the Administration requested $36.6 million — and presumably that is what will be spent by NSF — but the funding is still below the 1980 level of $47.9 million.

Among other decisions, both appropriations committees required that NSF should obtain their approval before spending money on the new ocean drilling vessel, *Glomar Explorer*. The conversion of the Central Intelligence Agency's vessel to a research ship has been very controversial and the committees wanted to see the results of the latest engineering studies. The $14 million requested to operate the existing *Glomar Challenger* was reduced to $12 million.

In September, just as researchers planning to go to Antarctica for the summer season were getting ready, the Senate Appropriations Committee cut the US Antarctic programme's $86.4 million budget request by $15.3 million. This reduction would have cut the season's scientific programme by 60 to 70 per cent. In the end, only $4 million was taken from the programme, leaving $73.4 million for running costs and $9 million for science. The cut will delay some construction planned for the base at McMurdo and mean later relief for the wintring-over parties in August 1983.

International programmes at NSF continue their recent decline, from $13.7 million in fiscal year 1980 to $9.1 million in fiscal year 1983. The foundation has circumvented the Administration's and Congress's dislike of international science by funding international scientific travel out of the regular research funds. But because it puts international travel in competition with so many other things, it may accelerate the well-documented trend of declining US scientific travel abroad and fewer promising young US scientists taking fellowships overseas. **Deborah Shapley**

Slaughter steps down

John B. Slaughter, director of the National Science Foundation, stepped down on 1 November in accordance with his decision several months ago to become chancellor of the University of Maryland College Park Campus. Since the Administration has not yet decided on a successor, Donald N. Langenberg, NSF's deputy director, is to become acting director of the foundation. Langenberg is likely to be a leading candidate for the position of director because of his extensive experience in various posts at the foundation.

Research on ageing

US physicians come to life

Washington

Research on ageing has received some welcome attention in past weeks. First there was a meeting about recent research findings held at Rockefeller University, New York and sponsored by FIBER, the Fund for Investigative Biomedical Research, a relatively new private organization sponsored by medical philanthropist Mary Lasker and others. Then, in late October, the Institute of Medicine (IOM) devoted a day of its annual meeting to ageing research and the challenge to the US medical systems of the growing proportion of old people in the population (see *Nature* 26 August, p.779, and 2 September, p.2).

Both meetings were rich in suggestions from researchers in other fields for possible lines of inquiry into the mechanisms of ageing and into ways of prolonging cellular life or at least retarding decay. For example, at the FIBER meeting, Dr Allen R. Goldstein, chairman of the biochemistry department at the George Washington University School of Medical and Health Sciences, described the progress that has been made recently in understanding of the thymus: some recent work suggests that thymosin, which has been used to restore the immune response in cancer patients treated with chemotherapy, could also boost the immune response in older individuals. Joan Smith-Sonneborn of the University of Wyoming, a zoologist, described how paramecia can repair their own DNA through photoreactivation, and thus live a little longer.

Professor James Williamson, of the department of geriatrics at the University of Edinburgh, talked about the social and financial problems posed by the large numbers of elderly people that will survive later in the century. Professor Williamson runs a geriatric service which consists of an interdisciplinary team of doctors and nurses. Patients referred to the service are visited at home within a day; only 30 per cent of them have to go to hospital and then usually for only a short time, or for regular short visits to give relief to their families. Such a service can reduce the number of old people in hospital geriatric wards by as much as 50 per cent.

A doctor from Los Angeles said that such a system would be impossible there, but Paul Beeson, editor of the American Geriatric Society's journal and formerly chairman of the department of medicine at Yale University medical school, disagreed. He said that most US doctors had their ideas of medicine shaped by the 1950s and 1960s, when funds were growing for biomedical research and specialities that could bring spectacular results were most sought after. Several leaders of US medicine have attacked the notion of geriatric medicine as not being medicine at all, he said, because it aims only to help people — and their families — and is more a social service than an investigative science.

Recommendations about how US medicine should address the problem of the nation's ageing population may emerge from a study that the Institute of Medicine and the National Academy of Sciences have set up and which is due to be completed next year. **Deborah Shapley**

Madrid conference

Failing hopes for agreement

The review Conference on Security and Cooperation in Europe (CSCE), which reconvenes in Madrid next week, seems fated to be as inconclusive as the previous gathering in Belgrade (October 1977–March 1978).

The implementation of the Helsinki Accords has, if anything been hampered by increasing international tension, and, in particular, the imposition of martial law in Poland. So far there has been no agreement on the further development of the CSCE process. A possible draft statement (Document RM-39) drawn up in December 1981 by the non-aligned and neutral signatories of the Helsinki Final Act remains in abeyance, because the delegations from the United States and its Western allies have so far refused to discuss it while the situation in Poland shows no marked improvement.

The linking of negotiations on security and economic and scientific cooperation with those on human rights is one of the most sensitive issues in the Helsinki process. During the drafting of the Helsinki Final Act, the various proposals for cooperation were divided into three large filing baskets — security and arms control (Basket I), economic, scientific and technological cooperation (Basket II) and human rights (Basket III).The contention of the United States and some of its Western allies is that the signatory states must implement all three baskets. The Soviet Union and socialist bloc, however, prefer to treat the three baskets separately.

After the Belgrade review conference, it was decided to hive off scientific and technological cooperation — then considered the least contentious subjects — into a special "scientific forum" in Hamburg, held a few months before the main conference opened in Madrid.

The contents of Document RM-39 are for the most part acceptable in principle to all sides, although some of the "confidence building measures" associated with Basket I would doubtless need further detailed negotiation. (Thus the French proposal for an extension of the zone in which the Soviet Union should notify major troop movements back to the Urals has been countered by a Soviet demand that the NATO powers should notify major naval movements in the Atlantic.)

The Helsinki process, however, as the United States in quick to point out, is not a matter of legal wrangling but the creation of an atmosphere of detente. In the absence of such an atmosphere, they stated last March, it is impossible to discuss RM-39 or any other draft agreement. Since then the international climate has deteriorated even further. United States sanctions against the trans-Europe pipeline has evoked Soviet criticism that the United States is deliberately trying to sabotage detente and urging that the pipeline is a success for Basket II.

The disappearance of the Helsinki Monitoring Movement in the Soviet Union (the last group, reduced by imprisonments to two members, dissolved itself last summer) is unlikely to improve the situation in Madrid. Nor is the recent renewed attack in the Soviet media on Anatolii Shcharanskii, a former member of the movement, now serving a 13-year sentence for human rights activities which the courts found treasonable. Nor is the arrest, in Poland, of the mathematician Dr Zbigniew Romaszewski, who in 1980 compiled and sent to Madrid a report on human rights abuses in Poland.

Under these conditions, it is uncertain whether any useful discussions can be expected from the forthcoming session. If the United States once again refuses to discuss Document RM-39, there would be little point in continuing the session. Sooner or later, if no final statement is agreed, the Madrid Conference will go the way of its predecessor in Belgrade; it will have to agree to disagree, and set a place and date for a new Conference. **Vera Rich**

UK university mergers

No links for UMIST and Salford

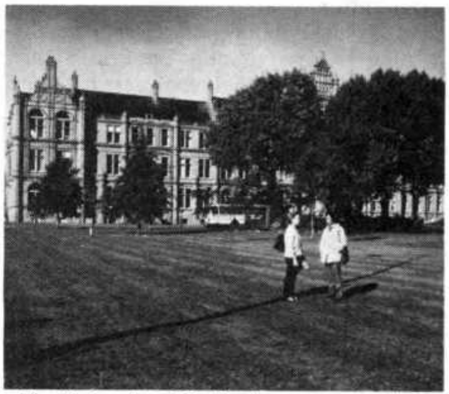
A combination of institutional loyalty and academic snobbery seems to have frustrated one of the most promising of amalgamations between British universities — a much canvassed proposal that the University of Salford and the University of Manchester Institute of Science and Technology (UMIST) should join forces. Two weeks ago, the UMIST governing body (its council) decided that, among several possible options, it would prefer to forge stronger links with its parent university, the University of Manchester.

Both partners in this abortive marriage have just lived through a hard year. Salford has been adjusting to the prospect of a sharply reduced subvention from the University Grants Committee (UGC), discovering that the extension of the transitional period has not allowed it to avoid painful retrenchment. UMIST, three miles away, has spent the past year wrestling with the problem of whether its principal, Professor R.N. Haszeldine, should remain in the post to which he was appointed in 1975. The cost of modernizing the principal's residence was a contentious issue. Professor Haszeldine, distinguished for his research on fluorine chemistry, has retired early with effect from the end of this year.

Almost immediately that issue had been resolved, UMIST found the local newspapers full of a proposal by Mr Fred Sylvester, one of Manchester's Members of Parliament, that Salford and UMIST should agree to merge. The logic of such an arrangement seems irrefutable; both institutions concentrate on science and technology (but have important outside interests, in politics and modern languages respectively, for example) while they are physically separated by only three miles.

The University of Salford now says it is disappointed that the prospect of a merger between the two institutions has disappeared. People at UMIST, on the other hand, profess themselves offended that they first heard of the proposed merger from newspaper reports, and that there has never been a formal approach from Salford.

The preferred option of the UMIST court to strengthen links with the University of Manchester, is intended to build on the institute's constitution as the Faculty of Technology of the university. The university awards degrees to graduates of the institute, but otherwise relations between the two over the past thirty years have been close or distant according to the personalities of those in charge. UMIST now cites as an example of the collaboration foreseen with its parent institution the occupation of the same building by two departments of metallurgy, its own and that of the university, saying that it has asked for further discussion of such cooperation.



The University of Salford — to remain alone

By common consent, Salford has survived the hardships of the past two years with flair, largely because of the success as vice-chancellor of Dr J. M. Ashworth, the most centrally placed (but not the most senior) of the British government's scientific advisers until the end of 1980. One Salford academic said this week that Ashworth has given Salford such a sense that it has a future that hope is now pinned on the belief that UGC will next year relent.

Both institutions are on course in their reduction of student numbers, while each of them has increased the intake of overseas students in the current academic year, Salford by 46 per cent and UMIST by half as much. ●

US medical schools

Counting social costs

Washington

There is a story making the rounds of college administrators in which a university president is greeted by the Devil at the gates of Hell with an offer of the presidency of the local university. Delighted, the president immediately accepts, remarking that he had expected far worse treatment. "Yes", Satan replies with a glint in his eye, "but our university has *two* medical schools."

If that is indeed the American university president's personal vision of hell, then some recent changes in government health-care financing may be a foretaste. Stanford University president Donald Kennedy, for one, has left no doubt that the federal government is taking the part of the Devil in imposing limitations on the reimbursement to hospitals for treating poor and elderly patients covered by government programmes.

Kennedy's views are shared widely among university-affiliated teaching hospitals, which see themselves as innocent victims of government's efforts to control rocketing health-care costs, and in particular those costs borne by the government itself.

In the past ten years, federal spending on Medicare (which covers the elderly through the social security system) climbed from $8,800 million to more than $44,000 million; spending for Medicaid (which covers the poor through the welfare system) rose from $4,700 million to more than $17,000 million. Even before the coming of Reagonomics, these seemingly uncontrollable expenditures were a matter of concern within Congress and the executive branch.

But to the universities, even these modest cuts have been a source of worry. According to a recent report prepared by the Association of Academic Health Centers, Medicare and Medicaid payments to university-affiliated teaching hospitals allowed them to expand their faculties and their educational programmes during the late 1960s and 1970s. This dependence has made them acutely sensitive to any efforts to limit reimbursements.

So, with some new and much tougher limitations in effect from 1 October, the complaints from universities have grown louder. Kennedy, in his Harvard speech, called the government policy "disastrous". The crux of the matter, he said, is that the government is no longer reimbursing hospitals for the full cost of Medicare and Medicaid patients. This forces the hospitals to raise their charges to private patients, and puts a disproportionate burden on teaching hospitals, which receive a high proportion of difficult and charity cases. Furthermore, the higher costs to private patients at teaching hospitals means that more of the routine — and profitable — business is going to county and private hospitals.

The shifting of costs from Medicare and Medicaid patients to private patients has been well-documented by the insurance industry, which ends up paying more. According to Neil Swan of the Health Insurance Association of America, the government shortfall will amount to $5,800 million this year. Kennedy said that charges to private patients at Stanford University Hospital could be reduced overnight by 14 per cent if Medicare and Medicaid reimbursements covered true costs.

And data from the Association of American Medical Colleges (AAMC) seem to support the universities' contention that they carry a greater burden than most. A comparison of the 327 member hospitals in AAMC with the 5,503 non-AAMC hospitals in the American Hospital Association found that although the teaching hospitals accounted for 26 per cent of total net patient revenue, they carried 35 per cent of bad debts and 47 per cent of the charity write-offs.

The new rules impose, for the first time, a limit on the annual increase in all hospital costs paid for by Medicare and Medicaid — a limit that will widen the gap between government reimbursements and the true costs of treating government-supported patients. The increase for 1983 has been set at 7.9 per cent; hospitals whose costs rise more than that will have to bear part of the excess themselves. The new rules also require that among groupings of similar hospitals, no-one can run costs greater than 120 per cent of the group's average. (That limit will drop to 115 per cent in 1984 and 110 per cent in 1985.) Together, these measures are expected to save $480 million in 1983 and $3,770 million by 1985.

The universities' complaints fall on less-than-sympathetic ears at the Senate Finance Committee, which, at the instigation of Senator Robert Dole (Republican, Kansas), wrote the legislation ordering the new rules. One staff member said "you hear that griping all the time", but that the rules contain several special provisions that favour the universities. Most important is exemption from the new limitations for direct educational costs of teaching hospitals, for example, interns' and residents' salaries.

The new rules do contain, however, a direct blow to one bountiful source of funds for the universities under Medicare and Medicaid: faculty practice fees. These are fees paid for the professional time of faculty physicians who treat Medicare and Medicaid patients. The faculty physicians turn these reimbursements over to the university, which uses them partly to supplement faculty salaries and partly for "dean's funds" that pay educational expenses, such as equipment purchases. Under the new rules, faculty practice fees cannot exceed the faculty member's salary.

The situation is complicated by a proposal made public earlier this month by Richard Schweiker, Secretary of Health and Human Services, that would completely overhaul the method of government payment under Medicare and Medicaid. This plan, known as "prospective reimbursement", would set reimbursement rates in advance. The most serious reservation is that, like the 1 October rules, it does nothing about the problem of the cost-shift to private patients. The insurance industry, which is particularly eager for action, points to successful state programmes (in Maryland and New Jersey, and soon in Massachusetts and New York) that combine prospective reimbursement with state regulation of charges to all patients.

Stephen Budiansky

Lead in petrol

Europe too soft?

Brussels

A new attempt is being made to revive the debate about lead safety levels by European consumer and environmental groups. Despite numerous directives defining safety levels in everything from the workplace to shellfish, EEC is now being accused of setting lower safety levels than either the United States or Japan. Calls for a revision of European standards of lead in petrol were made last week by European associations of consumer groups (BEUC) and environmental groups (EEB).

Since 1978, an EEC directive has permitted lead in petrol levels of a maximum of 0.4 grammes per litre and a minimum of 0.15 grammes per litre. The United Kingdom's decision to enforce the lower level from 1985 onwards aroused considerable controversy earlier this year because of scientific evidence that even low concentrations of lead in air could have harmful effects on the nervous system of critical groups such as children and pregnant women.

A new campaign is being launched to persuade the European Commission to revise the directive, and to introduce lead-free petrol throughout the member states. No member state is at present allowed to do this and pressure is building up from inside and outside the European Community. Germany and Denmark are in favour and Sweden, Norway and Switzerland are threatening to take unilateral action. The consumer and environmental lobbyists argue that if the two other main car-producing countries are convinced of the desirability of lead-free petrol, so should be the Community. Japan started as early as 1968 and the United States began to phase out leaded petrol in 1974, although small refineries are still allowed to produce leaded petrol.

Experience in both Japan and the United

0028-0836/82/440006-02$01 00

States suggests that there are few penalties for introducing lead-free petrol. The added cost to the consumer in the first two or three years is probably no more than £0.8 pence a gallon, according to the UK Ministry of Transport, while the lobbyists claim that studies in the United States and Canada prove that there are definite savings in vehicle maintenance costs of perhaps $0.05 a US gallon. In addition, European car manufacturers already make cars for the US and Japanese markets designed to run on lead-free petrol.

But industry is unlikely to be happy about being asked to make new investments when there is already a massive overcapacity in European refineries and the car industry is faced with a prolonged recession.

Their defence rests mainly on placing doubt on the scientific evidence of low concentrations of lead in air causing damage. While EEB and BEUC admit there is unlikely ever to be exact correlations between, for example a reduction of lead air concentration and the number of mentally subnormal children in the EEC, there is enough evidence to warrant action.

The Isotopic Lead Experiment being sponsored by the Commission in Turin and Piedmont indicates that at least 30 per cent of the lead in blood comes from petrol, although there are, of course, plenty of other sources such as paint or plumbing. In the experiment, lead from Broken Hill Mine in Australia with an easily recognizable mix of isotopes 206 and 207 was put in the petrol sold in the area between 1977 and 1979 thus enabling the source of the lead in blood to be immediately identified. The full report of the research has yet to be released on the grounds that there has been some difficulty in interpreting the data, but there are now rumours that the real reason is the alarming nature of the conclusions.

The arguments will undoubtedly continue, though, on what constitutes a safe level of exposure. This year EEC approved a directive for a maximum blood lead level of 60 microgrammes per decilitre in the workplace despite calls from the European Parliament and some member states for more stringent standards.

The European Commission wants to review the blood lead reference levels which are the criteria for assessing the need to take remedial action. The reference levels are a maximum of 20 microgrammes per decilitre of blood for 50 per cent of the population, 30 for 90 per cent and 35 for 98 per cent of the population.

The Lawther Report in the United Kingdom, published in 1980, asserted that there was no convincing evidence of deleterious effects below the 35 microgrammes per decilitre level. Yet an American study by Davidow *et al.* in New York in 1982 on the influence of lead on the production of haemoglobin suggests that the blood lead level threshold below which children's haemoglobin production is not affected is 15–18 microgrammes per decilitre.

Jasper Becker

Blue skies all around

The pace of industrial investment in British academic research seems to be quickening. After several years of niggardly treatment at the hands of the British taxpayer, British academics appear to be more willing than ever that their research should be supported by industrial money. This is the spirit in which British Petroleum's Venture Research Unit, formed by BP Limited two years ago to support what is called "blue skies research", decided to invest £500,000 in four novel academic projects, three in Britain and one in Austin, Texas.

The four contracts agreed upon last week (but yet to be negotiated with the intended recipients) illustrate what BP means by blue skies research. One, with the University of Aberdeen, is an exploratory project further to investigate the possibility that L-phase bacteria may be able to transfer genetic material directly into the cells of plants.

The venture unit is also offering research contracts to the University of Sheffield to investigate the application of control engineering methods to the study of photosynthesis and to the University of Dundee for an investigation of the apparently superior properties of amorphous silicon as a material for semiconductors. The proposed contract with the University of Texas, Austin, is for the development of the work of Dr Jess Kimble on optically bistable devices, possible components in future computers.

Some of the score or so of projects so far backed are relevant to the immediate needs of BP, which maintains its own much larger in-house research programme for that purpose. According to Dr D.W. Braben, the manager of the venture unit, the objective is to find people who are preoccupied with some unusual problem and who appear to have the ingenuity to solve it. Many of the contracts so far signed are concerned with the mathematics of complex processes, with computer applications and with the behaviour of microorganisms. Under the usual arrangement with an academic group, publication is allowed until commercial exploitation is foreseen.

The University of Sheffield is also the partner in another industrial venture announced this week — the founding of a company (Plant Science Ltd) to exploit several applications of plant science developed at the university's Institute of Biotechnology, founded with a grant from the Wolfson Foundation in 1978 and converted into an independent unit (with a further grant of £360,000) in March 1981.

The new company has been started with a capital contribution from TDC, described as "the high-technology arm" of Finance for Industry, a kind of merchant bank supported by various clearing banks. Among the objectives of Plant Science Ltd will be the development of plant varieties yielding substantial quantities of chemicals (such as steroids) and of processes for their extraction. The technical director of the new company is Dr Michael Fowler, from the university institute, who with Dr Anthony Jubb (recruited as managing director from ICI Ltd) will share part of the equity with TDC and the university. ●

UK research councils

Spend, spend, spending

Next to the cost of defence and of the police, the British science budget stands out in British public expenditure by having increased in the past three years even more quickly than the rate of inflation. Sir Alec Merrison, chairman of the Advisory Board for the Research Councils, said last week that "you cannot stay in that position without paying a price". Part of the price may be the publication last week of the board's advice on how to cut the cake (£507 million in 1983–84, 1.2 per cent more than needed to compensate for inflation).

The board has the following comments to make on the cases put to it by its pensioners, five research councils, the Royal Society and a museum.

The Agricultural Research Council (ARC) plans to maintain and even increase support for university research, especially in biotechnology, reproductive endocrinology, plant growth hormones and food process engineering. A new computer centre is planned. If there were more money (there is not) it would be spent on the genetic manipulation of animals, vaccine production and the micro-propagation of plants.

The board says that ARC should press ahead with its priority projects and should seek outside sources of financial support for some of this but recommends a constant cash contribution from the science budget in the next three years of £46 million. ARC's total income would increase from £95.9 million in the present financial year to £107 million in 1985–86 on the assumption that the agriculture ministry would pay more for commissioned research.

The Medical Research Council (MRC) plans a scheme to rescue biomedical research groups left stranded by university economics up to a total of 20 groups at a cost of £50,000 each in each of the next five years, and a modest increase of graduate student support. The council promises "major restructuring" at the National

0028-0836/82/440007-02$01.00

Institute for Medical Research and at its Radiobiology Unit, and clinical trials in such fields as cancer treatment, NMR imaging and multiple sclerosis.

The board recommends that MRC should "review" its participation in the European Molecular Biology Laboratory (Heidelberg), warns the council not to spend research funds in neglectful universities and recommends that the council should have a constant 22.5 per cent of the science budget, amounting to £113 million next year which will be increased by about £5 million from other sources.

The Natural Environment Research Council (NERC) plans to support more university research and graduate students, and to continue diverting resources towards remote sensing. Participation in the international ocean drilling programme beyond 1983 is uncertain, given the likely 50 per cent increase of cost.

The board recommends a share of the science budget rising from £58 million in 1983-84 to £63 million in 1985-86, including a constant £0.4 million for ocean drilling. At the end of the period, NERC will be £1.7 million worse off than now, but will earn £29 million from commissioned research.

The Science and Engineering Research Council (SERC) plans to increase support for biotechnology and civil engineering, to cut back in marine technology and polymer engineering, to reduce its payroll by 1 per cent in each of the next three years and to divert resources of two "major new programmes" — information technology and space research, perhaps at a total cost of £50 million over three years.

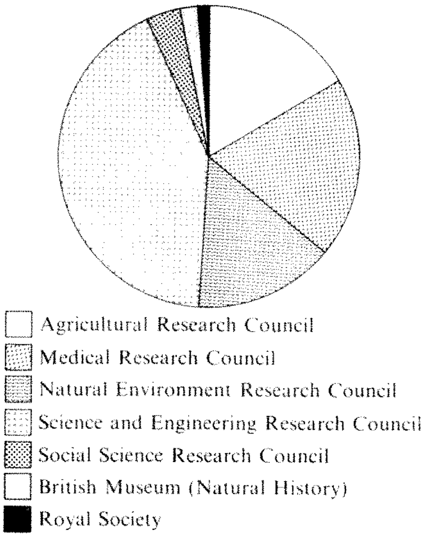
The board accepts that the time has come to halt the decline of "big science", recommends that the council should have an extra £22.5 million over three years to support basic research in information technology but that it should find the extra needed from its own resources. The board says that the council's budget should increase from £234 million now to £250 million next year and £278 million in three years, to which is added about £10 million in other income.

The Social Science Research Council (SSRC) pleads for a restoration of the funds cut from its budget in recent years, promising new research training schemes and boasting of a smoother organization. The board's recommendation accepts this case, suggesting a share of the science budget rising from £23.3 million next year to £25.5 million after three years. These are the sums from which the Secretary of State for Education and Science has subtracted in advance a total of £6 million. Sir Alec Merrison said last week that his board had no hard feelings on the subject, saying that the minister was the one with ultimate responsibility.

The British Museum (Natural History) asked the board for a general increase of funds to strengthen its general programme, and has been repaid with the recommendation that the proposed extension of the museum's exhibition space (at a cost of between £23 and £29 million) should be abandoned. The board says that the project, "however worthy, has no direct connection with scientific research".

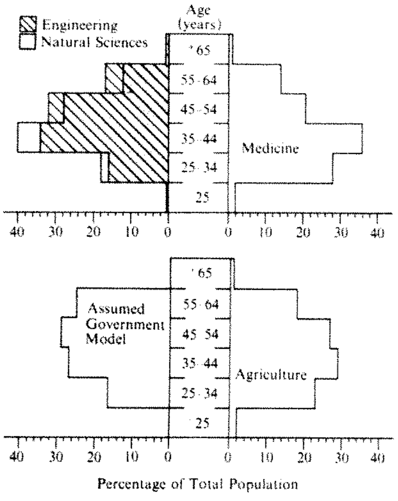
The Royal Society plans to spend £1 million a year on a scheme for 100 new research fellowships and asks for half that amount to support exchanges with the United States, while promising stronger collaboration with Japan. (The society laments that the Australian government is unwilling to help with the cost of the present Anglo-Australian exchange scheme.)

The board accepts the case that money should be spent on people rather than on instrumentation and project grants, and recommends an increase of £0.5 million in the society's budget to £5.0 million next year rising to £5.8 million in 1985-86. The society's total annual income is nearly £2 million greater. ●



Relative income of research councils, etc. in 1982-83. Figures include allocations from the science budget, commissioned research and other receipts. Total income is £579 million. (Source: *The Science Budget, a Forward Look*, the Advisory Board for the Research Councils.)

Age distribution in British academic disciplines.



Data from the ABRC report showing age distribution in various disciplines together with the steady-state distribution (bottom, left).

Environmental research at risk

Oceanography and forestry departments in British universities may be threatened by university efforts to trim spending in line with government cuts, according to Sir Hermann Bondi, chairman of the UK Natural Environment Research Council (NERC).

"It is of the utmost importance" writes Sir Hermann in the 1982 annual NERC report (HMSO, £4.25), published last week "that [the universities] manage their affairs in their present difficulties so as not to weaken their research capabilities . . .". Small fields, common to only a few universities, are particularly vulnerable, believes Sir Hermann — and he is clearly itching to tell the universities what to do without quite daring to. "Our ability to intervene and to help is clearly very limited" he writes. NERC has offered to help relocate departments from one university to another and to allow a degree of rationalization of resources in the universities — "but we must wait for their initiative . . .".

Sir Hermann has also had to wait for the initiative of certain government departments, not named in the report but certainly including the Department of the Environment, which have been very slow to define a long-term contract research policy. "Some of our customers find talking to us a little strange" said Sir Hermann last week. The strangeness is legal: advice has been given that a verbal agreement is as binding as a written one, with the result that "certain departments" have refused to discuss possible future funding or policy. This has led to considerable difficulties at NERC, which must assume that it always has the correct programme of basic research to provide expertise for any applied contracts that may be placed with it.

The Rothschild principle, where a portion of a research council's cash is obtained by contract from a customer department, was still "fundamentally right" said Sir Hermann. However, being right in principle was not sufficient — the department itself had to have great scientific competence. One of Rothschild's objectives had been to create that competence in the form of chief scientists' divisions — but in some departments the chief scientists had been pushed to one side. "They must be at the centre of decision-making" said Sir Hermann. The scientific attitude of the chief scientist should "permeate the whole department". **Robert Walgate**

US geological research

Asset-stripping fear at survey

Washington

It has been a long, hot summer for the US Geological Survey (USGS) the United States' oldest basic research agency. A chain of decisions by the controversial US Secretary of the Interior, James Watt — that stem from a scandal in one part of the survey dating back to 1959 — had led by 1 October to the departure of approximately 2,400 people, including the entire Conservation Division and a third of USGS's marine geology research, to a new agency in charge of leasing federal lands, the Minerals Management Service (MMS).

One survey scientist describes his organization now as "a car going down the street and someone takes a wheel off". By October, Dallas Peck, the director of the survey who is one of its career scientists, had adroitly negotiated with Watt, who is his boss, to minimize the damage to the survey as a research institution, and cut back the "raid" of marine geology from Watt's original plans.

The loss of only a third of the marine geology group was considered a triumph of sorts by survey scientists who, over the summer, had been comparing departure plans. Morale was described as good, even though rumours were still circulating that Watt might now also ask the coal and marine scientists at the survey to come over to the politically-led MMS.

USGS conducts basic geological research, but since the nineteenth century it has also had some applied missions. The most important of these, in recent years, has been to make geological assessments of federal and Indian lands, both in the "lower 48" states and in Alaska, and of the enormous US continental shelf. These assessments are used by another agency of the Interior Department, the Bureau of Land Management, to second-guess oil and minerals company bids to explore and develop these lands, and for devising overall policies on which lands should be developed. USGS had the job of determining the "fair market value" of the lands and of specific tracts, to make sure the government made the corporations offer high enough royalties to flow to the federal and state coffers.

Both these tasks have been intensely controversial, and pitted the Interior Department, the Bureau of Land Management, the government, the companies, the environmentalists and the Indian tribes against each other in a fashion that makes the development of the North Sea and northern Canada look orderly by comparison.

The misnamed Conservation Division of USGS had the job of regulation, including royalty collection. Geologists in the Geologic Division, which includes the marine geologists, dealt with resource assessment and determining fair market value.

Over the years, many lands were leased for oil and mineral development in the Western states, and after the discovery of oil at Prudhoe Bay, Alaska, and the 1973 oil embargo, the leasing of lands grew, as did royalties. The Conservation Division did not have the manpower to handle these tasks. When Watt took office in early 1981, he unearthed a series of old General Accounting Office reports dating back to 1959, claiming USGS had failed to collect enough money.

Watt appointed a commission, headed by a businessman, David F. Linowes, to look into the loss of revenues. In January 1982, acting on the Linowes Commission report, he decided to transfer the handling of royalties to a new agency, the Minerals Management Service. But he went further than the Linowes commission and moved the entire Conservation Division — approximately 2,200 people — to make the bulk of the new MMS. MMS would handle the assessment, leasing and royalties collection for offshore lands, as well as the assessment, monitoring and royalties collection of onshore lands. Its powers over the onshore lands may yet be increased.

The transfer of the Conservation Division in January made big cuts in USGS, which had 10,000 full-time positions, and a budget proposed at $516 million. But it was considered by many to be an appropriate streamlining of the offshore leasing process, which had hitherto required many different agencies (or as one source says "35 people in the room with Watt") to coordinate in order to issue a single lease.

Far more controversial was another directive — a surprise to USGS and, apparently, to its director, Peck — that Watt sent in May asking that the Marine Geology Division, which makes offshore resource assessments, should also move over to MMS. Although the marine geology work consists of only 442 full-time positions and funding of $22 million, the division considers itself part of the scientific heart of the survey. Everyone was upset at the thought of these people, who pride themselves on being as good as university professors, working for the political MMS, which is run by Harold E. Doley Jr, a 35-year-old black Louisiana stockbroker who had helped get southern black votes for Reagan in 1980.

"All of a sudden, MMS would acquire all those ships and photographic equipment and scientists who were more senior than most of the personnel of MMS" comments one survey scientist — indicating the shock caused by Watt's memorandum.

Peck, however (who could not be reached for interview), took the blow in his stride, and argued that the agency was stronger. To his staff, in May, he said that "the focus of our activities is now even more clearly upon the scientific and technical aspects of our mission . . . It is now our responsibility to assure that we continue to earn the confidence which the secretary has placed in us. This will require that we look carefully at everything we are doing to ensure that our actions are responsible to the department's goals."

Peck negotiated with his bosses at the Interior Department all summer, and by the summer's end had reached an agreement by which only those marine geologists who really were involved in resource assessment and applied jobs would leave the survey for MMS. Finally, only 147 positions and $8 million left the programme. According to an earlier plan, marine geology was merged with energy, within the Geologic Division.

Harold Doley Jr — MMS director

Watt explained to a group of visitors to the White House a few weeks ago his belief that the government must facilitate the orderly development of the country's mineral and energy resources to avoid a "panic" rush to develop them in the twenty-first century.

The controversy, and continuing fear of another Watt raid on other researchers, has been high drama for the Geological Survey, which enjoyed a carefully nurtured respectable obscurity around Washington. But there are more important issues at stake, namely whether assessment should be carried out within a scientific agency if it is to preserve its integrity.

One commonly expressed fear is that MMS will be so anxious to respond to Watt's wishes that it will undervalue the tracts and not require high enough bids from industry — thus depriving federal and state governments of revenue. It will be some time before it can be determined if this major shift in science policy is a mistake, and loses the taxpayer money. If it does, it will be an ironic outcome for a process that began by trying to recoup funds for the public purse.

CORRESPONDENCE

EMBL's databank

SIR — We have had several comments concerning the recent letter from A. Slocum (*Nature* 7 October, p.482) describing a commercial timesharing service offered by Intelligenetics, Inc.

Intelligenetics makes available extensive software and computing capacity together with two nucleic acid sequence databases, including the one maintained by our group at the European Molecular Biology Laboratory (EMBL).

We wish to point out that the EMBL sequence data library has been sent to more than one thousand organizations, both academic and commercial. The data collection is supplied to everyone on the same basis: no restriction is made on its use or redistribution. Intelligenetics is free to offer access to the data in the context of their computing system, as is anyone else who may wish to do so. No-one has special or exclusive licence to the data: they remain freely available to any individual or organization directly from us.

Greg Hamm
Kurt Stueber
Graham Cameron

Heidelberg, FRG

Keep the index

SIR — Having read King's critical comments (*Nature* 30 September, p.390), I would like to express my approval of your biotechnology stock index.

The success of these corporations will reflect the ability of biotechnology to find a place in public and private business. There are many more biotechnology corporations, some without public stock offerings, that are just as important. It is not necessary to list every firm to achieve a general overview, as *Nature* has done so well.

I hope *Nature* will not hesitate to add or drop corporations from the index in keeping with trends in this field.

Squizzle Plekavich

Arlington, Massachusetts, USA

Preventing wars

SIR — I was pleased to read that J.R. Skoyles (*Nature* 7 October, p.482) approves of the proposals for a "comprehensive ban on all methods and means of warfare specifically designed to kill or injure by inducing human disease".

I feel that the criticisms with which he continues his letter are based on a misunderstanding of the second part of my letter (*Nature* 9 September, p.102). It was concerned only with the disarmament side of the disarmament/international security relationship[1], as is the UN draft Comprehensive Programme of Disarmament (CPD). The draft was referred by the UN Second Special Session on Disarmament back to the Geneva Committee on Disarmament for them to bring a revised version to the 1983 regular Session of the General Assembly. We believe that the content of the draft should be a matter for informed public discussion and comment, and wish to contribute to encouraging this.

The approach in the existing draft CPD is across-the-board disarmament in three (or four) stages. The arguments against this approach are: a 50-year history of political failure; the unrealistic requirement diplomatically and technically for simultaneous negotiations and verifications in all five categories of disarmament measures of Stage I; requiring the final stage of nuclear disarmament to coincide with the final stage of conventional disarmament, despite uncertainty on whether world society can achieve the latter; and the preclusion of a selective comprehensive treaty banning non-nuclear weapons of mass destruction and all disease-inducing methods of warfare, which is the only immediately feasible treaty of comprehensive disarmament[2].

The specific measures mentioned in the second part of my letter were only suggestions of what hopefully might follow the conclusion of such a treaty, if the disarmament diplomats could be persuaded to replace their "disarmament in layers" by a more meaningful approach.

The fetal soul

SIR — I beg leave to disagree with the comment in your leading article that "gastrulation is the latest point at which twinning can occur and thus the first point at which one body can have a unique soul" (*Nature* 7 October, p.475).

In one of the most solemn declarations of the Catholic Church Pope Pius IX in 1854 declared:

> The blessed Virgin Mary was, in the first instant of her conception, through the merits of Jesus Christ the saviour of the human race, by a singular grace and privilege of God almighty, preserved immune from every stain of original sin.

It is thus certain for Catholics that the soul enters the fetus at conception. If the physical fetus divides, God is as capable of creating a second soul as He was of creating the first — thus both bodies will have immortal souls, each of which will eventually spend eternity in a state of friendship with God (Heaven) or enmity with God (Hell).

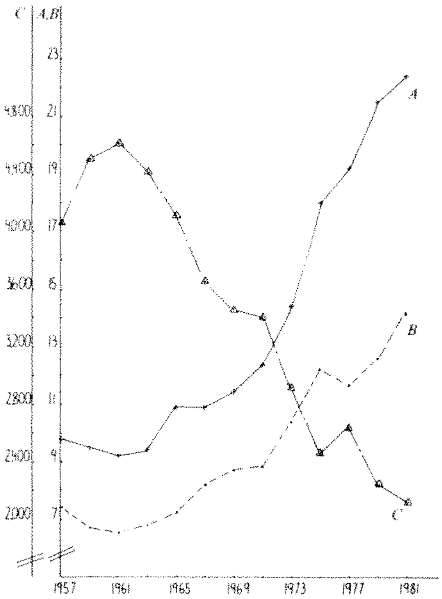
Costly journals

SIR — Robert Campbell was right to point out in an introduction to New Journals Review (*Nature* 7 October, p.49) that falling circulations do bring sharp increases in journal prices, thus causing a further drop in subscription levels, and further price increases. It is a problem we have been interested in for some time now[1] and have studied quantitatively in relation to physics periodicals. The problem facing libraries is indeed difficult. Taking our sample of 160 journals as an example, if a library wanted to keep up with both the growth in the number of core physics journals and their rising prices, it would have needed to increase its subscription budget by a factor of 30 since 1957.

We have shown elsewhere[3] that most of the price increases can be attributed to falls in circulations, but we have also demonstrated that, for the last few years, journal prices have been rising in anticipation of even greater circulation falls (see figure).

The timing of this change corresponds to a fall in the size of the market for physics journals. Unless some drastic steps are taken to reverse this trend, we predict that, as far as *physics* journals are concerned, the circulation will continue to fall[3]. By the year 2000, the average subscription level of a core physics journal will be approximately 900, a fivefold drop since the late 1950s. Prices will, of course, continue to rise.



Graph showing the impact of the fall in circulation on journal prices in a sample of 160 core physics journals. Scale *A*, the actual price per standard volume, in constant (1957) dollars; *B*, the "expected" price per standard volume, in constant (1957) dollars; *C*, the average circulation per title for journals in the sample. A standard volume contains 500 standard pages[1]. The "expected" price is calculated by taking into account increases in publishing costs and falls in circulation[2]. Note the increasing divergence of the two price curves.

NEWS AND VIEWS

How large is the Universe?

Estimates of the Hubble constant have fluctuated frequently in recent decades, usually between 50 and 100 km s^{-1} per megaparsec. There is still much to be done to fix the value.

Sir Hermann Bondi once caused great consternation among an audience of physicists by declaring that because the essential parameters of the Universe were then (in the early 1950s) so poorly known, and so likely to be wrong, he proposed to ignore what passed for numerical data in a lecture on cosmology. Since then, matters have to some extent improved. Since 1974, for example, a monumental study by Sandage and Tammann (see, for example, Sandage, A.R. and Tammann, G.A., *Astrophys. J.* **194,** 559; 1974) has seemed to provide a reasonably secure basis for estimating the distance scale of the Universe. To be sure, there has been a constant rumble of discontent with the resulting estimates, so much so that most articles dealing with distant phenomena have prudently included a statement of which estimate of Hubble's constant has been used in the interpretation of data. Now the issue will have been thrown into the melting-pot again with the publication by David A. Hanes of the Anglo-Australian Telescope of an argument that the extragalatic distance scale has been overestimated by 50 per cent or so (Hanes, D.A. *Mon. Not. R. astr. Soc.* **201,** 145–170; 1982).

Nobody is to blame. The problem of laying down a distance scale within the local galaxy, which occupied the best part of a century, was a sufficient illustration of the difficulties of such exercises. As things turned out, it may be counted simply luck that there is a class of stars, the Cepheid variables, whose period of variation is a function of their luminosity, and which can thus be used as milestones within the local galaxy. Experience has so far revealed no comparably convenient method for the measurement of extragalactic distances. Instead, people like Sandage have been forced to rely on much less sharp correlations between the characteristics of some distant galaxy and its probable luminosity. But only in the past decade or so has it become clear that the statistical distance yardsticks now developed are undermined at least to some degree by the likelihood that the galaxy from which all observations are made (our own), and the Local Group of galaxies to which it belongs, are probably moving towards the centre of the Virgo cluster, probably under the influence of gravitational attraction.

What Hanes has now done is to work step by step through the analysis by which Sandage and Tammann set up their distance scale ten years ago. There is no dispute about the distance to the galaxies belonging to the Local Group — the Magellanic Clouds and the Andromeda Nebula (M33) for example — for Cepheid variables are still recognizable there and can be used as more or less certain yardsticks. Moreover, these galaxies of the Local Group serve as proving grounds for other kinds of distance yardsticks — other kinds of variable stars, red giants and the like. Hanes now points out that the crucial step in the Sandage analysis is the extension of this kind of argument to the next nearest group of galaxies, that centred on the object known as NGC2403, for this is the most distant galaxy in which Cepheid variables can still be recognized as such. The essential difficulty is that light from these variable stars may be obscured to an unknown extent by the material of which the galaxy consists, thus reducing the perceived luminosity of the objects. Hanes follows others in arguing that too little allowance has been made for obscuration, with the result that the estimate of the distance of even NGC2403 has been overestimated.

The trouble with this conclusion, forcefully advocated by Hanes, is that it applies to the other tests used by those who set out to establish extragalactic yardsticks. One of the most obvious of these is based on the assumption that the brightest (and thus the most easily distinguishable) stars in a distant galaxy are likely to be indicators of the distance of that object. The more distant a galaxy, the fainter its brightest blue stars should seem to be. The obvious pitfall is that the brightest stars in a galaxy, lying as they must on the extreme tail of some gaussian distribution, can only be indicators of distance in some statistical sense. Mercifully, extragalactic yardstick-makers are reconciled to that. Hanes's particular contribution to this discussion is to show that the brightest star criterion depends on a piece of circular reasoning. Much the same is true, says Hanes, of the other criterion used as a distance marker by Sandage and Tammann — the notion that the size of molecular hydrogen clouds associated with galaxies should statistically represent their distance from the local galaxy (which implicitly supposes that while galaxies and their associated molecular hydrogen clouds may differ from each other in their extent, the range of this variation is not *too* great). Hanes finds himself putting the reasonable proposition that the visual appearance of a distant galaxy, which is a guide to its intrinsic luminosity in some poorly known statistical sense, may be a better criterion than any other used so far. The proposition is reasonable because it depends on integrated light intensity, not the luminosity of exceptional objects.

Hanes thus comes to the conclusion that the Hubble constant is more probably larger than smaller — more like 100 km s^{-1} per megaparsec than half as much. Indeed, he neatly splits the difference between the estimate of Hubble's constant published a decade ago and that of 100 km s^{-1} per megaparsec: if the measured redshifts of the Virgo cluster galaxies are taken at their face value, Hubble's constant probably lies within 12 units of 76 km s^{-1} per megaparsec, but if the Local Group is really moving towards the Virgo cluster, Hubble's constant is probably more like 100 km s^{-1} per megaparsec. This conclusion cannot easily be disputed; Hanes's own estimated errors are, with the benefit of recent observations, narrower than his predecessors have felt able to quote. One snag, of course, is that a large Hubble's constant means a younger visible universe, which raises difficulties for those concerned with the time needed for stellar evolution. But the conflict is not sharp enough to keep people awake at nights.

So what happens next? The ideal is that somebody should find a way of correlating some property of a distant galaxy with its intrinsic luminosity that will provide a distance scale as reliable as that of the Cepheid variables within the local galaxy; that would be sheer luck. Otherwise, further refinement will depend on more painstaking statistical analysis of that which Hanes describes. This is why Hanes's own account of his proof that Sandage and Tammann were mistaken is curiously sour — it is replete with words and phrases such as "wrong", "incorrect", "untested assumption", "gives no assurances of the correctness" and so on. Hanes has every right to be proud of his latest paper on the extragalactic distance scale, for it is a thorough piece of work. But is he right to be so scornful of those whose even more careful work made possible his provocative reanalysis? Even Newton, after all, acknowledged that he had stood on the shoulders of giants.

Trouble in the J-land

from Jan Klein and Zoltan A. Nagy

IMMUNOLOGY is not exactly noted for its lack of controversies, but the publication of the paper by Steinmetz and his colleagues[1] in this issue of *Nature* (p.35) gives the controversies a new dimension. The authors have cloned a piece of mouse chromosome containing the class II genes of the major histocompatibility complex (MHC) and report, among other things, that they cannot find at least two genes placed into this piece by immunogeneticists. Now, not finding a gene would not cause much of a stir — immunologists have been quite frivolous about putting genes into the MHC and then taking them out again — were it not for the fact that one of them is the so-called *I-J* gene (*J* for short).

The *I-J* gene was described by Murphy and his colleagues[2] in 1976. They produced an antiserum, [B10.T(6R) × B10.D2]F_1 anti-B10.AQR, which contained only antibodies specific for MHC class II antigens. Since at the time class II molecules (which provide a context for recognition of antigens by T cells; see *News and Views* **297**, 628) were believed to be present on B but not T lymphocytes, this antiserum was not expected to react with any T cells. However, when Murphy and his colleagues added it, together with complement, to a cell suspension containing suppressor T cells (cells capable of inhibiting the immune response of other cells), they discovered that the suppressive activity of these cells was abolished. When they then absorbed the antiserum by B10.A(5R) and B10.A(3R) cells, they found, to their surprise, that the former strain did and the latter did not remove the anti suppressor T cell activity. The result was surprising because the B10.A(3R) and B10.A(5R) strains had been thought to be identical in their MHC: both were derived by intra-MHC crossing-over from the same two parental strains, C57BL/10 and B10.A, and the recombinations were believed to have taken place in approximately the same region. If we designate, as was then the custom, the MHC genes of the two parents as K^b I-A^b I-B^b I-C^b S^b D^b (C57BL/10) and K^k I-A^k I-B^k I-C^d $S^d D^d$ (B10.A), then we can write the genotypes of the two recombinants as K^b I-A^b I-B^b I-C^d S^d D^d. The absorption data, however, indicated that the two recombinants were not identical and that the B10.A(5R) recombinant inherited from the B10.A parent something that the B10.A(3R) strain did not (the genotype of the B10.AQR strain, against which the antiserum was produced, is K^q I-A^k I-B^k I-C^d S^d D^d), and that this 'something' was controlled by a gene located between the *I-B* and *I-C* subregions. The authors designated this new subregion by the next available letter, *I-J*.

At the same time, another group of investigators — Tada and his colleagues[3] — reached a similar conclusion using a slightly different assay for the purportive J-specific antibodies. They reported earlier that the inhibitory activity of the suppressor T cells on other cells was mediated by a soluble factor. When they incubated the supernatant containing the factor with an antiserum similar to that used by Murphy and his colleagues, the supernatant no longer inhibited the response, presumably because the suppressor factor was removed by the J-specific antibodies.

These discoveries were quickly confirmed by other laboratories and the J-specific antibodies became firmly entrenched in the mouse MHC map and in immunologists' minds. Eventually at least one commercial company began selling anti-J sera and at least two reports appeared in the literature describing the production of J-specific monoclonal antibodies[4,5]. The original observations were then extended and the J determinants demonstrated on suppressor T cells and factors in a variety of systems. It appeared that not all suppressor T cells carried the J determinants and, in fact, the determinants were soon accepted as markers for a subpopulation of suppressor T cells. On the other hand, the determinants were also found on certain helper T cells and on macrophages. Furthermore, the J determinants were reported to stimulate mixed lymphocyte reaction, to restrict the interaction of suppressor and helper T cells, to be involved in the potentiation of immunity against syngeneic tumours, to govern the induction of immunological tolerance, as well as to do other remarkable things (see ref.6 for review). We have not counted the studies in which J-specific reagents have been used but there must be several hundred of them. In this situation, to question the orthodoxy of the *J* locus is likely to be regarded by many immunologists as a heresy of the most dangerous kind.

Yet, from the beginning, one could have had reservations about the *J* locus. For example, although J-specific antibodies had a potent effect in biological tests, they were extremely difficult to work with in serological assays. Some laboratories reported success in detecting J determinants by serological methods[7-9] but in most immunologists' hands, the cells binding the J-specific antibodies could not be visualized. The explanation offered was that the J determinants were only on a small subpopulation of lymphocytes and that the reactivity with these cells was obscured by the background reactivity of the serological assays. However, suppressor T cells can be enriched and purified and J determinants have been reported to be expressed by permanent cell lines and clones[10,11], so on these cells there should not have been any difficulty in detecting these determinants serologically. Even more disturbing was the fact that no one had succeeded in isolating the J molecules from the cell membrane. Here again, the availability of lines purportedly expressing J molecules should have provided suitable material for this isolation. Finally, there was the difficulty of the interpretation of the *J* locus. The designation *I-J* implied that *J* was a class II locus but, as we have pointed out on another occasion[12], there was no good reason for this classification. At best, the J determinants could be regarded as markers for a subpopulation of certain immune cells, but that they functioned in the same way as class II determinants do has never been satisfactorily demonstrated.

The situation with the other missing gene — the ***B*** gene — is far more clearcut than that with the *J* gene. The ***B*** gene was invoked to explain a particular pattern of responsiveness to a small number of antigens, a pattern involving the strains already mentioned, as well as another intra-MHC recombinant, B10.A(2R)[13]. No other trait could be associated with the ***I-B*** subregion and no B-specific antibodies could be produced by cross-immunization of strains purportedly differing at the ***B*** locus. Only a few immunologists felt compelled to invoke the ***B*** gene and when they did, it was only because they did not bother to think of a better explanation. That an alternative explanation did exist and that it was far more attractive than the old one was demonstrated by Baxevanis and his colleagues[14]. These investigators showed that the same pattern of responsiveness can be obtained without the postulate of the ***B*** gene but with the assumption that suppressor cells are involved in the control of the response. They then went on to accumulate convincing evidence that the alternative explanation was indeed the correct one.

Steinmetz and his colleagues have now laid the lingering apprehension about the *J* and *B* loci to rest. They have isolated the DNA from the B10.A(3R) and B10.A(5R) strains, the two strains that were used to define the *J* locus genetically, and have been able to ascertain from which parent the DNA segments around the purported *I-J* subregion have come. As expected they have found that the left-hand (centromeric) segment of these recombinants is derived from the B10 parent and the right-hand (telomeric) segment from the B10.A parent. Between these two segments they have found a region whose origin they cannot determine, and it is this region that should contain not only the *J* but also the *B* locus (in the rest of

---

Jan Klein and Zoltan A. Nagy are in the Max-Planck-Institut für Biologie Abteilung Immungenetik, Corrensstrasse 42, 7400 Tübingen, FRG.

0028-0836/82/440012-02$01.00

the DNA, the B10.A(3R) and B10.A(5R) are identical). The trouble is that this middle region is only 3.4 kilobases long and at least part of this length constitutes another gene, the well defined E_β gene. When one subtracts the minimal sequence that apparently is E_β, all that is left for the *J* and *B* genes is a sequence of less than 1,000 nucleotides. Such a sequence is, of course, far less than is required for any full-fledged gene, not to mention two such genes. It may, in fact, turn out that the B10.A(3R) and B10.A(5R) strains have identical or nearly identical DNA sequences around the site where the crossing-over occurred. In plain language, it may turn out that the *J* and *B* genes do not exist in the place where they were supposed to be. What the Steinmetz study already clearly establishes is that if the *J* and *B* genes do exist in this region, they must be quite unusual genes.

Steinmetz and his colleagues offer some graceful and some not so graceful ways out of this dilemma. The one possibility that they do not consider is that the *B* and *J* genes simply do not exist. For the *B* genes, this possibility is not difficult to accept: after the demonstration by Baxevanis and his colleagues[14] that the *B* locus is an illusion generated by a particular type of interaction between the suppressor and helper T cells, there has really not been any justification for keeping this locus in the MHC map. But the *J* gene? Is it possible that here, too, immunologists have fallen victims to some other kind of illusion? □

Mapping the Universe

from Virginia Trimble

OUR inventory of basic kinds of objects and structures in the Universe is probably not yet complete, even on the largest scales. Thus participants in IAU Symposium 104 on 'Early Evolution of the Universe and its Present Structure'* heard of a new class of radio sources, of changes in our best estimates of irregularities in the 3K microwave background radiation, and much debate on the morphology and origin of superclusters of galaxies and the relative voids between them. The other main topic of discussion, exotic physics in the very early universe, was recently reviewed in these pages by Barrow and Turner[1].

For a quarter of a century the counting of radio sources has been telling us both about the nature of the sources and the large-scale structure of the Universe[2]. Essentially, as we count from the brightest sources towards fainter ones, we at first see more sources than expected if the objects are distributed uniformly in euclidean space, and then later we see less sources than would be predicted. J. Peacock (Royal Observatory, Edinburgh) reiterated the standard interpretation — powerful radio sources in elliptical galaxies and quasars were commoner in the past than now, but that very few turned on before the time corresponding to a redshift of about 4. P. Osmer (CTIO, Chile), A. Braccesi (University of Bologna) and A. Savage (UK Schmidt Telescope Unit) reported optical searches for quasistellar objects reinforcing this conclusion, though the last of the three groups involved has just reported a new record quasar redshift[3], $z = 3.78$ for PKS2000–330.

But, as we look to still fainter radio sources, the downward trend of number versus apparent brightness ceases, according to a new series of source counts, carried out at 1,412 MHz by R. Windhorst and others at Westerbork, and reported by H. van der Laan (University of Leiden). The most likely interpretation of this flattening in number versus flux is a new class of radio sources, which van der Laan called 'Population II radio galaxies'. They make up some 75 per cent of the sources seen at 1,412 MHz fluxes near 1 mJy, and their optical identifications are typically faint, fuzzy blue galaxies of unknown type. The radio morphology is both less tidily structured and smaller ($\lesssim$50 kpc) than that of brighter sources. The clustering properties are unknown. Van der Laan said that the new sources might be either spiral galaxies at redshifts near 0.4 or (at long last) the radio emission from so-called radio-quiet quasars, since the luminosity function is much like that of standard radio sources, except it is fainter by a factor of 1,000. The IR colours, according to Windhorst, divide into two classes, resembling those of giant elliptical radio galaxies and of less luminous spiral galaxies respectively. E. Fomalont and J. Wall presented results of an NRAO survey at 6 cm that also shows some flattening of number versus flux at the lowest flux levels surveyed and thus provides independent evidence of this (or at least some) new population of sources.

Looking for structure in the 3K background radiation is necessarily a less ancient activity than counting radio sources, though it is coeval with the discovery of the radiation itself[4]. N. Parijskij (Special Astrophysical Observatory), F. Melchiorri (Rome), D. Wilkinson (Princeton University), K. Kellermann (NRAO) and A. Lazenby (Jodrell Bank) reported on searches for anisotropies on various size scales and at various wavelengths carried out in the USSR, Italy, the US and Great Britain. The main conclusions follow.

First, the dipole anisotropy, attributable to our motion relative to the particles that last scattered the radiation, is here to stay. Though there is still some discrepancy between the Berkeley and Princeton results (owing, apparently, to calibration errors), we can say that the Sun is moving at 372 ± 25 km s^{-1} towards right ascension 11.2 h, $\delta = -6°$. This translates into a ~ 600 km s^{-1} velocity for the Local Group of galaxies, aimed about 30° away from the Virgo cluster, and so is at least roughly consistent with the result reported by J. Mould (Kitt Peak) from optical observations of galaxies of a few hundred km s^{-1} infall towards Virgo plus ~ 180 km s^{-1} rotation around it. The dipole anisotropy shows a small variation with a period of one year. Copernicus was right!

Second, the quadrupole anisotropy reported by two groups[5,6] has gone away and was apparently an artefact of improper subtraction of the contribution from continuum radiation by our own Galaxy. It has left behind a bright spot outside the galactic plane in the 0.6–2 mm data of the Rome group[7] but not in the longer-wavelength data from Berkeley and Princeton. Wilkinson suggested the hot spot might be thermal radiation by a large galactic dust cloud, though Melchiorri suspects it may have cosmological significance.

Third, on smaller scales, there continue to be mostly upper limits, $\Delta T/T \leq 3 \times 10^{-4}$ for 1′ to 1° scales from the NRAO and Jodrell surveys and $\leq 3\text{–}5 \times 10^{-5}$ on similar scales from the Rattan 600 (USSR) survey. G. de Zotti (University of Padova) suggested that the second of these limits could not be correct, because known radio sources alone should contribute larger fluctuations; and the American and British observers expressed audible curiosity about how the measurements were made. Parijskij's response was that the Rattan telescope is simply more suitable than most others for work on extended emission. Even the higher limits are already serious constraints on our models for cluster/galaxy formation because they pertain to the angular size of clusters at the

largest redshifts at which adiabatic perturbations in the matter density can begin to grow — we must have reasonable lumpiness then to get the lumpiness we see now. Ways out of this dilemma include, according to E. Salpeter (Cornell University), B. Jones (University of Paris), S. Bonometto (University of Padova) and N. Kaiser (University of Cambridge), an initial spectrum of fluctuations whose shape was not a power law; re-ionization at $z > 10$ to smooth out the lumps in the radiation but not the matter; galaxy and cluster formation by some process that makes the necessary lumps after recombination, as suggested by Ostriker and Cowie[8]; massive neutrinos, which can begin to clump as much as they want without distorting the radiation once they stop interacting with the photons (which happens much sooner for them than for ordinary matter); or non-adiabatic perturbations (which are, however, not permitted by modern grand unified theories[1]).

On all scales, we cannot hope to do much better than present accuracies and limits, which, according to Wilkinson, are within a factor of 3–4 of noise levels.

The study of superclusters (clusters of clusters of galaxies) and the voids between them is the oldest of all these activities; for, as J. Oort (University of Leiden) pointed out, their existence and main properties are already implicit in the Shapley–Ames catalogue[9] of 1932. There is general agreement on the existence of structures of up to 100–150 Mpc, separated by about twice that amount. The structures are at least somewhat elongated, with crossing times on the long axis greater than or approximating the age of the Universe and 10^{15}–10^{17} the mass of the Sun. And the density contrast between supercluster and void is sufficient (at least factors of 2–4) that we see some deceleration of the general Hubble expansion of the Universe at the edges. The chief observational items of dispute are (1) just how empty are the voids, (2) whether the typical supercluster shape is an ellipsoid, a pancake, or a string, and (3) the extent to which the superclusters join up into a network or cell structure. These bear directly on the chief theoretical question of how the superclusters formed. The competing models present explanations in terms of gravitational clustering of smaller-scale structures or fragmentation within pancake-like gas sheets formed by nonlinear growth of adiabatic perturbations.

Both models can make superclusters with roughly the correct size and correct first- and second-order correlation functions[10]. But the pancake models should result in emptier voids, more stringy features and more networking than the clustering models[14,15].

Looking into the voids, S. Shectman (Mt Wilson) reported an extension of the Kirshner *et al.*[11] redshift survey that confirms the existence of a sphere 120 Mpc across (for $H_0 = 50\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$) centred at right ascension 15 h, $\delta = +50°$, $V_r = 15{,}000$ km s^{-1} in which the density of galaxies is at most one quarter that of the surroundings. In fact, they find no galaxies at all in that sphere, though there are apparently modest numbers of emission line galaxies[12,13] in adjacent zones previously thought to be empty.

As far as shapes of superclusters go, our own Virgo one is a 6:3:1 ellipsoid according to R. Tully (Hawaii). But it is apparently far from typical. J. Einasto (Tartu) and F. Shandaring (Institute of Applied Mathematics, Moscow) reported applications of a new (to most astronomers!) technique, called percolation theory[16], which is particularly suited to determining topology (degree of connectedness) of structures, rather than just the amount of clustering. The primary conclusions are that the basic structures are strings of clusters and galaxies with a filling factor of about 1 per cent; that essentially all the strings are connected into a network; that the luminosity contrast between strings and voids is at least 10^3, though there are small strings within voids like the one of Kirshner *et al.*[11]; and that no one model copes simultaneously with all the data.

Finally, R.H. Miller (ESO and University of Chicago) showed cinematically the results of assorted numerical clustering experiments, some of which seemed to the eye to have produced much the same sorts of filaments and cells as seen in the distribution of real galaxies, though this has not yet been tested by percolation theory or anything similar. But he left us with the important thought that, just because simulation of a process produces something that looks like the real world, this does not necessarily mean that nature did it that way! □

Air pollutants act in combination

from J.N.B. Bell

NEW work from the University of Lancaster reported in this issue of *Nature* (p.55) highlights the importance of the combined effects of NO_2 and SO_2 — Britain's two most widespread air pollutants — in reducing the growth of grasses and trees. The work demonstrates the complexity of growth responses to SO_2/NO_2 mixtures and the danger of attempting to predict injury in the field on the basis of the single harvest fumigation experiments which are invariably employed as the basis for developing air-quality criteria.

Whitmore and Freer-Smith[1] fumigated *Poa pratensis* (meadow grass) and cuttings or seedlings of six tree species, *Malus domestica* (apple), *Betula pendula* (silver birch), *Betula pubescens* (common birch), *Populus nigra* (black poplar), *Alnus incarna* (grey alder) and *Tilia cordata* (small-leaved lime), for up to eleven months in outdoor glass chambers, in the presence of SO_2, NO_2, and SO_2 and NO_2 at concentrations (0.062 p.p.m.) encountered in some urban regions. Growth rates were compared with those of plants in clean air.

When *P. pratensis* was fumigated overwinter, the three gas treatments produced markedly different results between November and February — SO_2 had relatively little effect, NO_2 stimulated growth, and the mixture produced a substantial fall in dry weight. The greater than additive effect of the gas mixture subsequently disappeared, and reductions in growth became apparent in all treatments, although they recovered to the same level as the controls by June. A shorter summertime fumigation of the trees produced a greater than additive effect with SO_2 and NO_2 in four out of the six species.

That the air of suburban areas of British cities contains pollutants that can cause large reductions in the growth of grass species has been demonstrated by comparing the growth of plants grown in chambers ventilated with ambient or clean air[2-4]. Such effects may occur when the mean SO_2 level is much lower (0.011–0.026 p.p.m.) than that which reduces plant growth in fumigation experiments (≥0.038 p.p.m.)[5], suggesting that the fumigation design does not take into account the

0028-0836/82/440014-02$01.00

presence of other pollutants and the continuous fluctuation of SO_2 in ambient air[6].

Relatively recently, fumigation experiments have begun to be carried out using continuously fluctuating pollution levels. Two recent reports, however, indicate that the occurrence of peak concentrations of SO_2 may not be as important as has been suggested. Fumigations of ***Phleum pratense*** (timothy) with 0.06 p.p.m. SO_2 for 41 days produced the same effects on growth, irrespective of whether the pollutant was administered at a constant level, or with peak concentrations of 0.4 and 0.8 p.p.m. respectively[7]. Similarly, when ***Pinus sylvestris*** (Scots pine) seedlings were fumigated over 650 days with 0.038 p.p.m. SO_2, given either at a constant level, or as four treatments comprising factorial combinations of high (0.281 p.p.m.) and low (0.113 p.p.m.) hourly peaks over short (5 h) and long (21 h) periods, the constant treatment resulted in a 14 per cent reduction in dry weight increment, and peak concentrations did not produce any further growth reduction, unless they were of 21 hour duration[8].

It thus seems likely that the presence of other pollutants, in addition to SO_2, is a major factor in reducing plant growth in cities. High-temperature combustion processes produce abundant quantities of nitrogen oxides (NO_x), which have hitherto been little studied, expect for their role in the formation of photochemical oxidant smogs. NO_x is emitted into the atmosphere mainly in the form of NO, irrespective of whether the source is motor-vehicle exhaust or coal/oil-fired power stations, but is rapidly oxidized to NO_2. The limited data available show that mean NO_x levels are equal or greater (v/v) than mean SO_2 concentrations in both urban and rural areas. A SO_2/NO_x ratio of 1:1.5 has been recorded for central London[9] and it has been suggested[10] that approximately 11 per cent of rural land in western Europe may be exposed to SO_2 and NO_2 concentrations of > 0.038 and > 0.042 p.p.m. respectively. Clearly there is a need for the incorporation of NO_2 (and possibly NO) into fumigation experiments designed to investigate SO_2 effects on plants. Both additive and more than additive responses have been observed for SO_2/NO_2 mixtures on different grass species[11] but the work of Whitmore and Freer-Smith demonstrates for the first time that such effects are markedly influenced by season.

Considerable difficulty has been experienced in determining thresholds for long-term SO_2 injury to grass species[12]. Interactions between changing environmental conditions and SO_2 effects have been suggested as the main factor obscuring a clear dose–response relationship. Whitmore and Freer-Smith have identified another important factor, by showing that SO_2, NO_2 and their mixture have very different effects if the fumigation is terminated at different times of the year. Their work demonstrates the need for further such long-term experiments, with harvesting at intervals and, if possible, extension over several growing seasons in order to determine the net result of the positive and negative growth effects of the pollutants. □

Transformation and gene organization in *Drosophila*

from Michael Ashburner

THE highlight of Crete III, the third EMBO-sponsored workshop* on the molecular biology of *Drosophila*, was, without doubt, the announcement by G. Rubin and A. Spradling (Carnegie Institution, Baltimore) that they had successfully transformed *Drosophila* with exogenous DNA — results that have just made their appearance in *Science* (October 22, p.348). Moreover, D. Ish-Horowicz (Imperial Cancer Research Fund, London) reported that, in collaboration with J. Sang's group (University of Sussex), the transformation of *Drosophila* tissue culture cells with DNA had also been achieved.

The flies were transformed by the injection of exogenous DNA into embryos using the transposable P element as a vector. The P elements of *Drosophila* are repetitive genetic elements found only in certain strains (so-called 'P' strains) and absent from other ('M') strains. In hybrids between a P strain and an M strain, the P elements contributed by the P parent may become highly unstable (especially if the cross was between a P father and an M mother), to produce the syndrome of hybrid dysgenesis (see *News and Views* **299**, 676; 1982).

Rubin and Spradling constructed a vector that contained a wild-type *rosy* gene sequence within a P element sequence. Flies mutant for *rosy* have brownish eyes, since they lack the xanthine dehydrogenase (XDH) needed to synthesize the normal red eye pigments. *rosy* is particularly useful for this sort of experiment as only a few per cent of normal XDH activity is necessary to ensure a wild-type eye colour and the gene need not be active in the 'correct' tissue (or, perhaps, even at the 'right' stage of development) for a wild-type eye colour to result. Two successful methods of transformation were described. In the first, rosy-P plasmid was injected into embryos that were both mutant for *rosy* and carried their own integrated P elements on a dysgenic background. In the other, the rosy-P plasmid was co-injected with a cloned intact P element into non-dysgenic, and non-P-carrying, embryos. The introduced *rosy* genes integrated into the genomes of their hosts and at least one was active enough to ensure a wild-type eye colour.

The only other genes which have, so far, been used to transform flies are those coding for the egg-shell proteins. These are of particular interest for they amplify during normal development in the ovarian follicle, the tissue that secretes the egg shell. Spradling discussed the results of transformation with two different egg-shell protein gene fragments. In the transformed fly strains, three to four copies were integrated at various chromosome sites. One of these fragments amplifies according to its normal developmental schedule, despite its unusual location in the genome. This promises to be a powerful method for the study of those sequences responsible for the normal tissue-specific amplification of these genes.

Transformation was not, of course, the sole topic of discussion in Crete. Studies on the molecular organization of genes in *Drosophila* now seem to indicate that there are several different discrete categories of gene. The simplest are those present in a single copy. Only two have been reasonably well characterized — *rosy* (coding for XDH; W. Bender, Harvard Medical School) and the gene for alcohol dehydrogenase (T. Benyajati, Frederick

---

*The 3rd Workshop on 'The Molecular Biology and Developmental Genetics of Drosophila' was held at Kolymbari, Crete, on 21–26 June 1982 and was sponsored by EMBO and the University of Crete.

Michael Ashburner is at the Department of Genetics, Downing Street, Cambridge CB2 3EH.

Cancer Institute, Maryland; M. Ashburner and colleagues, University of Cambridge).

Yet even these genes may not be that 'simple'. At *Adh*, for example (Benyajati; N. Spoerel, University of Cambridge), transcription occurs from two quite different promoters in different tissues and at different stages of development.

Several 'complex' genes — complex in terms of their genetic organization and their developmental phenotypes — have been identified by *Drosophila* geneticists. Some of them are now cloned: *bithorax* (Bender; M. Akam, University of Cambridge; R. Saint, Stanford University), *Notch* (M. Young, Rockefeller; S. Artavanis-Tsakonis, Yale University), *scute* (J. Modolell, University of Madrid) and *rudimentary* (K. Louis, Princeton University) are examples. All are very large (*scute* is spread over at least 60 kilobases) and all produce a bewildering variety of developmentally regulated transcripts — at least four have been found at *scute*, each with quite different developmental specificities.

A third class of gene may be called 'clustered multicopy'. The copy number is low, from two to less than ten, the copies are all contained within a relatively short stretch of DNA (few tens of kilobases) and the different copies have often diverged so that they code for different, but functionally related, proteins. Several examples are known: the four genes coding for the small heat-shock proteins (E. Craig, University of Wisconsin-Madison), three genes coding for salivary gland glue proteins (E. Meyerowitz, Caltech) and the two major chorion protein gene clusters (Spradling; F.C. Kafatos, Harvard University) are well worked out. Presumably the members of a cluster are related by descent. However, not only are they often transcribed from different strands of the DNA but the extent of divergence since their presumed duplication may be considerable. Of the three different glue genes, one codes for a protein of 284 residues and the other two for much smaller proteins (about 50 amino acids). The large protein consists of four domains — a hydrophobic leader, 44 amino acids very high in threonine, 37 copies of a five-residue repeat and a C-terminal domain of 50 residues, very high in cysteine. The small proteins 'simply' lack the internal two domains! (Meyerowitz).

A fourth class of gene is the 'dispersed multicopy'. Again copy number is low, less than ten, but the copies are dispersed around the genome. If there are rules governing their location we do not know them yet. Examples are the actin genes (N. Davidson, Caltech), the genes coding for the larval serum proteins (four genes; D. Roberts, University of Oxford) and the *Hsp68* and *Hsp70* heat-shock genes and their cognates (Craig). Again, studies of the different copies suggest that they have evolved by duplication. Presumably (but not necessarily) they have been dispersed subsequently by a transposition process. Why some genes should be organized in small clusters and others dispersed is not yet clear. Of course some genes, for example, *Hsp 70*, share characteristics with both classes, being dispersed clusters. Finally, there is the class of tandemly repeated, high-copy number genes such as those coding for the rRNAs and the histones.

A fascinating family of transposable elements (TE) has been discovered by Bender. Called 'gypsy', they are often associated with spontaneous mutations that share the property that they can be suppressed by a recessive mutant allele of *su(Hw)*. Presumably gypsy acts at a distance, since revertants of some gypsy-associated *bithorax* mutations are only partial losses of the gypsy element itself. The suppressor does not act by causing the element to excise. Of quite a different order from these elements is G. Ising's (University of Lund) TE, which is vast (» 100 kb) and carries at least two enes (*white* and *roughest*). R. Paro (University of Basel) has cloned some examples of this TE: its transposable property apparently results from long 'fold-back' sequences at its ends. This 'FB-NOF' sequence also occurs elsewhere in the genome, for example the unstable *white-crimson* mutation is associated with this element.

Although molecular biology dominated the meeting it must not be thought that the gene-jockeys had it all their own way. An elegant demonstration of the error of inferring too much from the phenotype of mutations in a complex eukaryote such as *Drosophila* came with B. Baker's (La Jolla) study of mitosis in a random selection of conditional lethal mutations. Many had been selected for some 'interesting' developmental phenotype, for example an absence of imaginal disks. A suprisingly high proportion of the mutations turn out, however, to disrupt mitosis and some are very dramatic — accumulating over 1,000 chromosomes per nucleus. All diploid cells are affected. Although the mutants were originally called 'diskless' because this is the most prominent feature of their phenotype, they are clearly not 'imaginal disks' mutations in anything but a rather trivial sense.

The vigour of modern *Drosophila* biology was evident at Crete. The discovery of new molecular and genetic techniques cannot but fail to keep *Drosophila* research in the forefront of modern biology. This, and the patronage of the Crete meetings by the Bishop of Kastelli Kissamou, augurs well for Crete IV. □

Food — the best medicine

from Ben J. Miflin

EVERY so often society rediscovers the obvious. Currently many sections of society from Wall Street to Westminster are rediscovering plants and man's dependence on them. The waves of enthusiasm emanating from the new converts have led to the founding of numerous companies in the US and may yet be strong enough to push the British Technology Group into launching Celltech's country cousin (*Nature* **297**, 5; 1982). But where to sail? What to do? What to improve? Many think-tanks have pondered these questions and the CIBA Foundation* has recently broken its long-standing tradition of medically based symposia to address the topic of 'Better Crops for Food'.

First, define 'better', define 'food'! The answer depends on where you are standing and on how carefully you look at a particular agricultural system (C. Spedding, University of Reading). An apparent improvement may work in one context, be irrelevant in another and be absolutely disastrous in a third. Only if there is some appreciation of how the different systems work is there a chance of predicting, usually on the basis of modelling, what the effect of a development might be or which changes might be desirable.

Man has catalogued only a proportion of the world's plant species and he depends on 15 or so for the bulk of his agriculture (E. Bell, Royal Botanic Gardens, Kew). Many plant species are being lost irretrievably and these include reservoirs of germplasm relevant to our crops. However, what and how we should conserve is a matter of controversy. One answer may be the application of cryogenic techniques for storing plant tissue cultures (K. Dougall, University of Tennessee), but predicting what may be useful in the future is uncertain. New crops may emerge but the conservatism of agricultural and cultural practices limits likely crops to those which are already grown to some extent in marginal areas. The winged bean (*Psophocarpus tetragonolobus*) is one likely candidate; it seems to have many virtues including protein-rich tap roots and metre-long pods that can be eaten green or dried (N. Haq, University of South-

---

* The Ciba Foundation meeting on 'Better Crops for Food' was held 14–16 September. The proceedings will be published as Ciba Symposium 97 (Pitman Books).

Ben J. Miflin is in the Biochemistry Department, Rothamsted Experimental Station, Harpenden, Hertfordshire AL5 2JQ.

0028-0836/82/440016-02$01.00

ampton; S. Karikari, Ahmadu Bello University, Nigeria). Traditional intercropping systems practised in developing countries may also be a more appropriate guide to future cropping systems than western monoculture, as studies at ICRISAT have shown (R. Willey, University of Reading). The advantages may not be restricted solely to the tropics as mixed cropping of cultivars of barley and wheat, developed to combat disease, may yield more even in the absence of disease (P. Day, Plant Breeding Institute, Cambridge, quoting results of Wolfe).

The aims in breeding better crops are usually maximum yield (although maximum financial return may be better), disease resistance and nutritional quality. Improved yield has generally resulted from improved harvest index rather than from changes in carbon dioxide fixation rates. Nutritional quality in legume seed depends on many components (D. Boulter, University of Durham) and genotypes of soybeans lacking some of the undesirables ones have been found (T. Hymowitz, University of Illinois). Whether it is worth incorporating these traits into commercial cultivars depends on the rest of the diet, how the beans are cooked and whether the components confer pest or disease resistance on the seed.

Increases in yield, particularly of cereals, has resulted equally from improved cultivars and improved agronomic practice. Classical agronomic research started in the UK at Rothamsted with the aim of improving soils to fit the needs of the crops available. The approach may be curtailed in the future by the lack of energy to produce fertilizers (E. Bell), although others (R. Hardy, Du Pont, Wilmington; B. Miflin, Rothamsted Experimental Station) argued that this was unlikely as these inputs are a minor part of fuel use and often produce a positive energy return. Replacement of nitrogen fertilizer for cereals, by introduction into them of nitrogen fixation genes or by the use of associated symbioses, is unlikely other than in the very long term. However, rhizosphere microorganisms, including *Azospirillum*, may have an important role in enhancing nutrient uptake by crops (R. Hardy). Crops can also be tailored for the soils we have, whether they are naturally high in aluminium as in Brazil or made saline by continual irrigation as in California (E. Epstein, University of California, Davis). Energy to process crops into food may be the major input in both developed and developing countries; in the former it is often unnecessarily excessive, in the latter it can be a matter of life or death as when cooking inactives toxins. Developing countries are also suffering an energy crisis due to the destruction of trees which, for many reasons, are important components of agricultural systems (P. Nair, International Council for Research in Agroforestry, Cambridge).

Thus there is no lack of problems. But what of new tools to tackle them? The microchip makes computing on the farm possible and many systems are being developed to maximize efficient use of inputs; one such — EPIPRE — was described by J. Zadoks (Wageningen Agricultural University, The Netherlands). This predicts the optimum amount and timing of the use of crop-protection chemicals on a field-by-field basis. The result is mostly to reduce the amounts applied, thus reducing cost and preventing pollution — still further reductions will come with improvements such as electrostatic spraying. Practitioners of genetic engineering techniques, despite the current enthusiasm, generally do not see the dramatic production of 'super-plants' in the near future. What these techniques will do is improve our understanding of plant genetics and provide technical short-cuts for breeders. Flavell (Plant Breeding Institute, Cambridge) decribed two such applications for recombinant DNA techniques: for rapid measurement of genetic diversity in order to recognize desirable types and for a quick and sensitive assay to detect plant viruses. Each technique could shorten the long time required at present to breed new varieties. 'Intermediate' technologies which may be of short-term significance are those which produce genetic diversity, such as 'somaclonal' variation. This term, coined by W. Scowcroft (CSIRO, Canberra) describes the variation released during de- and re-differentiation of plants through protoplast and tissue culture techniques which is currently being assessed for commercial promise in several crops. Further down the line are protoplast techniques, including somatic cell fusion, which have the promise of transfer of desirable traits across the barriers of sexual incompatibilities (O. Schieder, Max Planck Institute für Zucktungsforschung, Cologne).

By way of conclusion, Spedding's quotation from Poul Andersson seems appropriate "I have never encountered any problem however complicated which, when looked at in the proper way, did not become still more complicated". In producing more food to meet the demand of the world's rapidly rising population there is no one problem, no one answer, only an almost infinite range of possibilities. In these circumstances research priorities should be diverse enough to provide various alternative solutions to the most likely crises. Evidence that this is the route to success comes from plants themselves, as E. Bingham (University of Wisconsin-Madison) elegantly showed. Lucerne cultivars bred for maximum heterozygosity have maximum vigour; dependence on a narrow (genetic) base leads to weakness and depression. □

100 years ago

A Curious Halo

THERE appeared in Nature, vol. xxvi. pp.268, 293, two articles headed "A Curious Halo," which reminded me of an analogous and still more curious phenomenon occurring sometimes here in China, during the hot season. I beg to hand you a few lines on that subject, from the *Monthly Bulletin* of the Zi-ka-wei Observatory for August, 1877.

"A phenomenon to which I wish to call the attention of meteorologists was obseved many times during that month (August), as also in July. It does not seem to take place in Europe, and I am inclined to think that it cannot occur except with an atmosphere over-charged with aqueous vapour, as it is the case with us in July and August. In the evening, just after sunset, or in the morning even long before sunrise, no matter what the direction of the wind and the barometric pressure may be, provided the day or night were very warm, *bands* of a tint varying from the faintest to the deepest *blue* are seen to appear upon the whitish or roseate vault of heaven. They usually are first seen in the east at evening and in the west at morning time, seemingly radiating from a common centre diametrically opposite the sun's position. At other times they emerge from the very position of the sun, or from both points at once, the interval being either free from bands or completely encircled by them.

"Last year (1876), on the morning of September 4, I enjoyed a most interesting sight. It was about 5 a.m., the moon, then on her nineteenth day, was above the western horizon, and just being partially eclipsed; now from her bright disc, as from a radiating centre, shot out a number of those bands or blue beams; they traversed the whole expanse of the sky, and seemed to converge towards a point whose situation in the east below the horizon corresponded with that of the moon in the west above the horizon.

"The bands or shoots are more or less numerous, bright, and persistent; some have been observed in the evening, fortyfive minutes after sunset, and in September, 1876, I saw them appear with the first break of day. They are evidently movable in the sky, and there is no doubt that they are due to comuli floating about the horizon. below or above, through which the light of the sun is sifted and split; they are, in fact, nothing else than the twilight. According as the clouds before the sun are more or less compact or loose, the bands may be blue, white, or red. More than once also have I seen the sky half white and half blue, the separation of the two colours being plainly perceivable, and Venus shining brilliantly in the blue sky close to that limit, whilst it would probably have been almost invisible through the milky sky hard by."

Any one who gazes for the first time at this beautiful phenomenon cannot help wondering and acknowledging it to be greatly different from anything to be seen elsewhere. It is quite certain that the phenomenon is due to the atmospheric vapour, but I am rather at a los to give a more satisfactory explanation. The dispersion of the direct rays of the sun *into* the minute drops resulting from a partial but wide-spreading condensation of the aqueous vapour in the upper strata of the air, might account for evening time. Besides, the interposition of a light cloud in the way of the sun's rays does not impair the transparency of the drops, and the blue sky may be visible. Now, in the morning and evening the rays of the sun are almost parallel with the horizon; they traverse the whole expanse of the sky, and their apparent convergence on the both sides is only due to the same optical illusion which shows us the two rails of a railway track or the walls of a tunnel as converging.

Fire deaths and toxic gases

from Barbara Chernov Levin

AMONG the industrialized countries which record statistics on fires, the United States has the most fires per capita. The rate of fire death in the United States is almost twice the international average and is surpassed only by Canada[1]. In 1979, approximately 7,800 people died and another 31,000 were reported injured[2]. Direct dollar loss was greater than $5 billion, but when indirect costs (meeting fire codes, installing fire protection systems, supporting fire departments and insuring property) are included in this calculation, the annual cost of fires in the United States is estimated at more than $20 billion.

Large fires receive the most public attention and media coverage; for example, three hotel fires between November 1980 and May 1981 were the cause of 119 fire deaths and more than 1,000 injuries. Residential fires, however, continue to be the cause of most fire deaths and injuries. Approximately 80 per cent of these fire deaths are not due to burns, but are attributed to inhalation of toxic smoke and hot gases[3]. This information has prompted the fire community, materials manufacturers and building code officials to pose the following questions: do some building materials and furnishings produce combustion products that are much more toxic than others, and how can the occupants of buildings be protected from unnecessary risk in case of a fire? The answers to these questions are not simple and involve the evaluation of the total toxic hazard generated by a fire.

The potential for generating toxic gas from burning materials has long been recognized; for example, in the 1929 Cleveland Clinic fire, 123 people were killed by the decomposition products of nitrocellulose X-ray film[4]. Only recently, however, has the fire research community become acutely aware and concerned about the problem of the toxicity of combustion products and the possibility that toxic gases other than carbon monoxide (still a primary toxicant in fires) may have an important role. Autopsy data show a sample of fire victims with less than lethal amounts of carbon monoxide in their blood[3,5,6]. Other factors may have been involved, however, as some of the victims had pre-existing heart disease and/or alcoholic intoxication.

Laboratory research studies also suggest a role for toxicants other than carbon monoxide. A highly toxic bicyclic phosphate compound produced during the thermal decomposition of a laboratory-formulated rigid flame-retarded polyurethane foam was identified by the University of Utah[7] and suggests the need for an animal testing system — conventional chemical techniques would have failed to detect such an unusual toxic product. Moreover, scientists at the National Bureau of Standards have found that carbon monoxide concentrations measured at the LC$_{50}$ of twelve thermally decomposed materials were 60–4,400 p.p.m., whereas the LC$_{50}$ of pure carbon monoxide was 5,000 p.p.m. The LC$_{50}$ here measures the amount of material necessary to kill 50 per cent of the rats exposed for 30 min. The death of the rats at less than the LC$_{50}$ of pure carbon monoxide indicated that additional toxic gases or other factors (for example, heat, lowered oxygen concentrations) were contributing to the cause of death. Many of the exposed rats also died during a 14 day post-exposure observation period, an occurrence which cannot be directly attributed to carbon monoxide poisoning.

Some of these thermally decomposed materials also produced the potent toxicants hydrogen cyanide and/or hydrogen chloride as well as carbon monoxide. Chemical analysis has detected many combustion products in addition to the frequently examined toxicants — carbon monoxide, carbon dioxide, hydrogen chloride, other halogens, oxides of nitrogen and sulphur, and ammonia. Scientists at the Fire Research Station in England have identified 20 chemical species from the thermal decomposition of polyacrylonitrile and 30 combustion products from polypropylene[5]. Michal *et al.* have identified 71 compounds from the combustion of polyethylene and 55 compounds from polypropylene[9]. Wood generates at least as many products[10]. The relative contribution of one or various combinations of these combustion products to animal toxicity is so far unknown and would require a major research effort to decipher.

The current awareness of the importance of combustion product toxicity is apparent from two recent symposia (Annual Society of Toxicology meeting, February 1982; American Chemical Society national meeting, March 1982), and by the newly convened combustion product toxicity commitees of the US National Fire Protection Association and of the US National Institute of Building Sciences. Recently, three different animal-based test methods designed to assess the acute inhalation toxicity of combustion products were proposed to the Committee on Fire Standards of the American Society for Testing and Materials for their consideration. Worldwide concern about the toxicity of combustion products is indicated by increased activity in a Subcommittee on Toxic Hazards of the Fire Test Committee of the International Organization for Standardization and the development of separate tests in Germany, France, Japan and Belgium.

All these tests provide information on the acute toxicity resulting from the inhalation of combustion products, but each test is performed in different laboratory decomposition conditions. The tests do not address the problem of the total toxic hazard which a fire produces or the contribution of a material (or product in its actual end use) to that hazard under a 'real fire' situation. Nonetheless, some building code officials and state regulators are anxious to evaluate the combustion product toxicity of materials and are examining these test methods with that end in mind. It is important, however, that the acute toxicity (the harmful effects measured by the response of laboratory test animals to a single short exposure to combustion products generated by the thermal degradation of materials in specified conditions) be distinguished from the toxic hazard (the materials's properties and the environmental conditions which increase the probability that a toxic atmosphere will occur and an injury will result). Since any one fire is a dynamic, changing condition and no two fires are alike, no one test can duplicate all 'real fires'. Typical fire degradation modes (smouldering, radiant heat, non-flaming and flaming) can be reproduced in the laboratory, however, and materials can be tested in these conditions. The resultant laboratory toxicity data and other needed information, such as the projected end use of the product, the quantity of material present, its ignition and combustion properties, ventilation conditions, and the density and sensory-irritant properties of the smoke, may then be related to the total toxic hazard. Many of the investigators involved in this area of research are now turning their talents towards the more challenging field of toxic hazard analysis. ☐

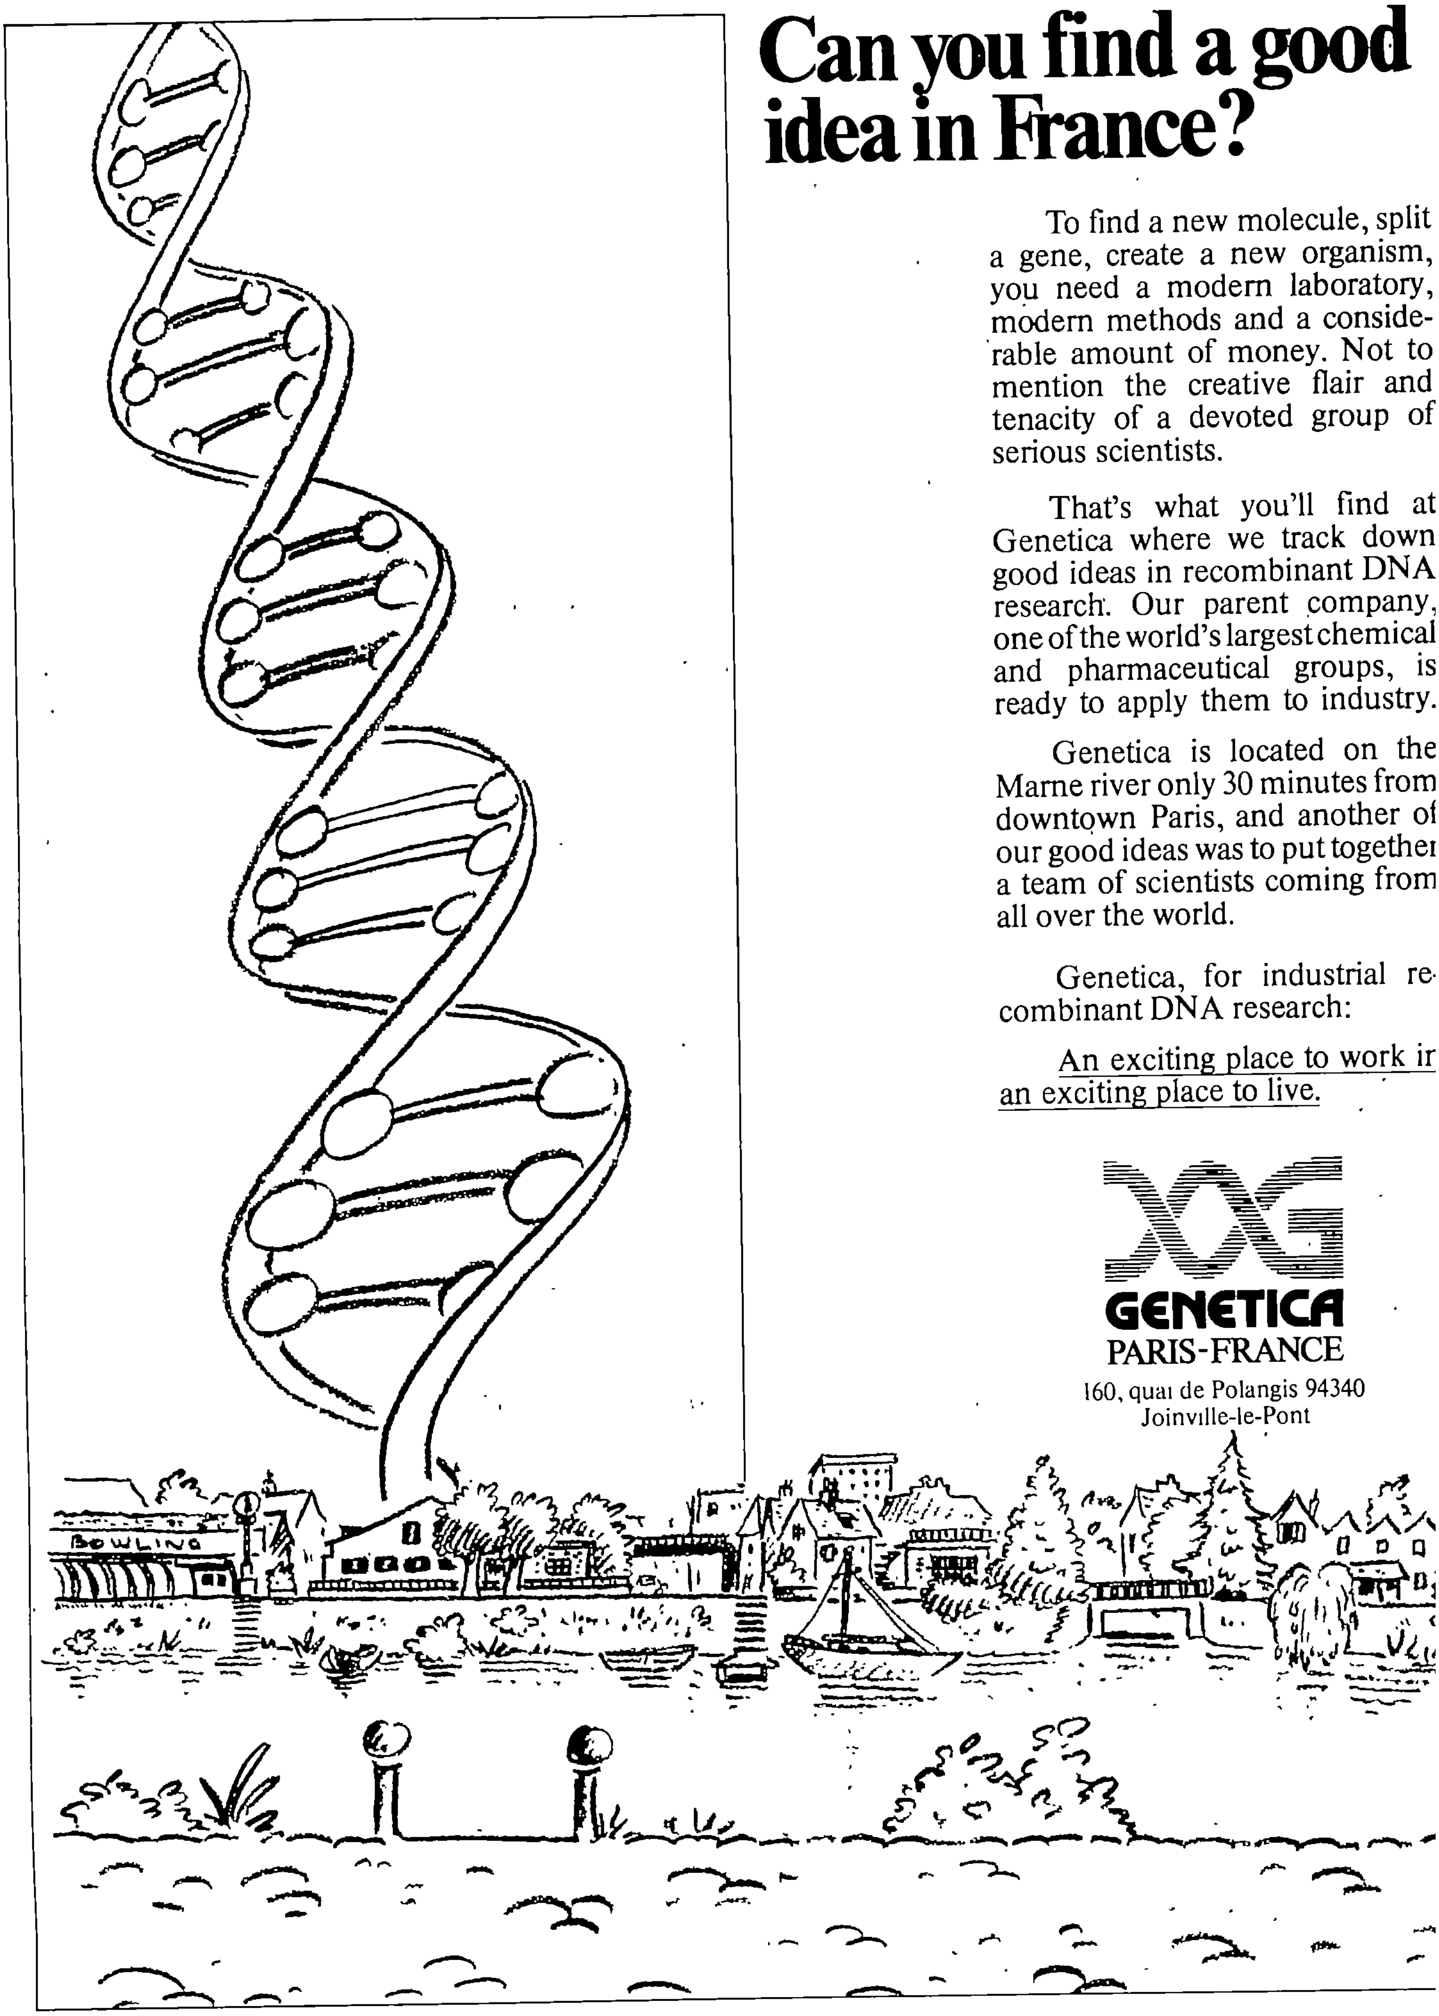
Can you find a good idea in France?



To find a new molecule, split a gene, create a new organism, you need a modern laboratory, modern methods and a considerable amount of money. Not to mention the creative flair and tenacity of a devoted group of serious scientists.

That's what you'll find at Genetica where we track down good ideas in recombinant DNA research. Our parent company, one of the world's largest chemical and pharmaceutical groups, is ready to apply them to industry.

Genetica is located on the Marne river only 30 minutes from downtown Paris, and another of our good ideas was to put together a team of scientists coming from all over the world.

Genetica, for industrial recombinant DNA research:

An exciting place to work in an exciting place to live.

Genetic and molecular mechanisms of viral pathogenesis: implications for prevention and treatment

Bernard N. Fields & Mark I. Greene

Departments of Microbiology and Pathology, Harvard Medical School and Department of Medicine (Infectious Disease),
Brigham and Women's Hospital, Boston, Massachusetts 02115, USA

The pathogenesis of infection of mice by the mammalian reoviruses involves several discrete steps. Each of the three viral outer capsid proteins has a highly distinct and specialized role: one protein (σ1) binds to cell surface receptors; a second protein (μ1C) determines the capacity for viral growth at mucosal surfaces; and the third protein (σ3) is responsible for inhibiting cell macromolecular synthesis. A detailed picture of the molecular basis of reovirus virulence and attenuation is now emerging.

TECHNOLOGICAL developments over the past decade have enhanced our understanding of the biochemical basis of heredity and have led to an increasing understanding of the organization and regulation of eukaryotic genes. Although microbial systems have provided many of the models for these basic studies, the complex nature of the interactions between microbial agents and eukaryotic hosts that occur during the infectious process have hindered the deciphering of the molecular mechanisms involved in infectious diseases[1]. Thus, while many elegant studies have been performed on the descriptive aspects of the pathogenesis of infectious diseases, little is known about the precise molecular events responsible[2]. Recently, increased knowledge of the functions of individual components of viruses and bacteria and their interactions in the ultimate production of infection have begun to allow research directed towards defining molecular mechanisms of pathogenesis[1,3,4].

Here we review studies using the mammalian reoviruses as a model of microbial pathogenesis. We shall describe the role of various viral components in the pathogenesis of reoviral infection of young mice, and illustrate several specific genetic and immunological manipulations which yield attenuated viruses. One of the major goals of studying viral pathogenesis with model systems such as the reoviruses is to understand the processes of attenuation and immunization of microbial pathogens and to develop new methods for the prevention and treatment of infectious diseases.

Reovirus structure and morphology

Genome structure. The mammalian reoviruses include three serotypes[5]. The viral genome consists of three size classes of segmented double-stranded RNA (dsRNA): large (L), medium (M) and small (S), each of which consists of unique segments[5]. L contains three genome segments (L1–L3) with molecular weights of ~ 2.3–2.5×10^6; M consists of three genome segments (M1–M3) with molecular weights of ~ 1.4–1.6×10^6; S has four genome segments (S1–S4) with molecular weights of ~ 0.6–0.9×10^6. Each of the 10 genome segments represents a single gene which is transcribed and translated into a unique mRNA molecule and a primary polypeptide, respectively[6–9].

Virion polypeptides. Solubilization and separation by polyacrylamide gel electrophoresis of the proteins in cells infected with reovirus yields three size classes: large or λ (λ1, λ2, λ3), middle or μ (μ1/μ1C, μ2, μNS), and small or σ (σ1, σ2, σNS, σ3)[7]. Nine of the polypeptides are present in purified virions (λ1, λ2, λ3, μ1/μ1C, μ2, σ1, σ2 and σ3) while two are found exclusively in the cytoplasm (μNS, σNS)[8,9]. The μ1C polypeptide is derived by cleavage from the primary μ1 polypeptide[5]. The correspondence between genes and proteins is shown in Table 1.

Morphology. Reovirions are icosahedral virions comprising a double capsid(s), which consists of a core containing the 10 genome dsRNA segments and a closely applied inner protein shell surrounded by an outer protein layer. The polypeptides in the core include λ1–λ3, μ1, μ2 and σ2 (refs 5, 8). The core contains the viral transcriptase and replicase[5]. The outer capsid shell consists of three polypeptides σ1, μ1C and σ3 (Fig. 1). Protein λ2 is exposed on the outside of the virus, and is thought to represent the core spike[10]. It is closely associated with σ1, the viral haemagglutinin (HA)[10]. The two major outer capsid polypeptides are μ1C and σ3; these are complexed to each other and are found in a 1:2 ratio in the virion[5].

Role of outer capsid in pathogenesis of reovirus infection

The pattern of virulence of the mammalian reoviruses is determined primarily by the three outer capsid polypeptides (μ1C, σ1 and σ3)[3], each of which has a unique role. Following entry into the gastrointestinal tract (the presumed natural portal of entry), the μ1C protein is digested by host cell proteases. It is this that induces, in part, the cellular immune response[11]. The σ1 protein (the viral haemagglutinin) interacts with receptors on the surface of immune and non-immune lymphocytes and neurones and in this way determines cell and tissue tropism[12–16].

Table 1 Correspondence between reovirus dsRNA genes and polypeptides

Gene segment	Polypeptide	Location in virus
L1	λ3	Core
L2	λ2	Core spike
L3	λ1	Core
M1	μ2	Core
M2	μ1/μ1C	Outer capsid
M3	μNS	Nonstructural
S1	σ1	Outer capsid
S2	σ2	Core
S3	σNS	Nonstructural
S4	σ3	Outer capsid

0028–0836/82/440109—05$01 00

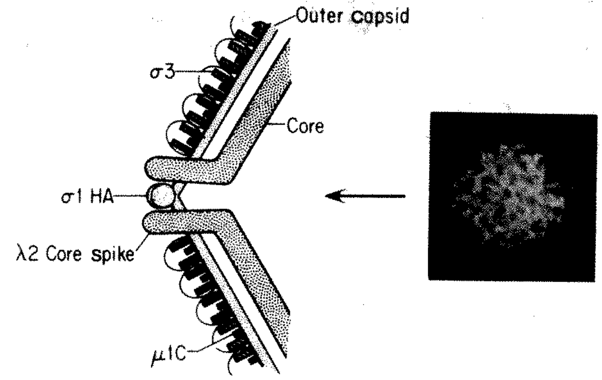

Fig. 1 Schematic diagram of the outer capsid of mammalian reovirus serotype 1, 2, 3. On the right is a negatively stained electron micrograph of an intact virion. On the left is a tentative schematic drawing showing how the three outer capsid proteins ($\sigma 1$, $\sigma 3$ and $\mu 1C$) and the core protein ($\lambda 2$) are organized on the outside of the virion: $\sigma 1$ is located at the vertices of the icosahedron close to $\lambda 2$, the core spike. $\mu 1C$ and $\sigma 3$ are associated with each other on the flat surface of the icosahedron.

It is the major antigen determining specific antiviral humoral or cellular immune responses. The $\sigma 3$ protein is responsible for inhibiting host cell RNA and protein synthesis and has a critical role in allowing the reovirus to initiate persistent infection of cultured cells[17,18].

Clearly, the three polypeptides of the outer capsid have different functions. Thus, altering any of them affects the behaviour of reoviruses in distinct ways (Table 2). The relevance of such an alteration to attenuation will now be reviewed in some detail for each protein.

Attenuation of mammalian reoviruses via the viral haemagglutinin ($\sigma 1$)

Allelic substitution. The major function of the haemagglutinin of reovirus in viral pathogenesis is determination of cell and tissue tropism. Intracerebral (i.c.) inoculation of newborn mice with type 3 reovirus leads to the development of an acute encephalitis that is uniformly fatal and associated with specific viral replication in neurones but not in ependymal cells[19,20]. In contrast, inoculation of type 1 reovirus causes a non-fatal acute ependymitis without involvement of neurones[21]. Localization of the different types of reovirus to different cells is determined in both cases by the $\sigma 1$ protein encoded by the *S1* gene[16,22]. Thus, substitution of the type 3 *S1* gene by alternative allelic forms of *S1* (from either type 1 or 2) can attenuate the highly virulent type 3 infection by targeting virus to less lethal sites[16]. It is important to emphasize that this kind of attenuation is associated with differences in specificity of the immune response of the host. The *S1* gene product is the antigen that evokes the major type-specific humoral and cellular immunological responses[13-15]. As immunity is type-specific, an infection with a reovirus containing a type 1 *S1* gene does not result in protective humoral or cellular immunity for reoviruses having different type 2 or 3 *S1* genes.

Selective mutations in the *S1* gene. To better define the functions of the viral haemagglutinin, we isolated several monoclonal antibodies directed against the $\sigma 1$ polypeptides[23]. As reovirus type 3 is 'neurovirulent', we concentrated largely on analysis of this serotype. We discovered several functionally distinct antigenic regions on the haemagglutinin, one of which is the major site recognized by neutralizing antibodies[23]. The same site is involved in the recognition of the reovirus type 3 haemagglutinin by cytolytic T lymphocytes (CTL), since the neutralizing monoclonal antibody blocks the interaction between such cells and reovirus[25].

As this site on $\sigma 1$ plays such a critical part in recognition of reovirus by the host immune system, we wished to determine whether it also has an important role in the interaction of reovirus with non-immune cells such as neurones. We reasoned that if the neutralization site of the viral haemagglutinin is involved in binding to receptors on the surface of neurones, variants resistant to neutralization by monoclonal antibodies might lose the capacity to bind to, or enter, neurones. When we isolated such variants by collecting those viral clones which grew in the presence of neutralizing monoclonal antibodies[24] and inoculated them into suckling mice, they were found to be either avirulent (lethal does for 50% of the population, $LD_{50} > 10$) or markedly reduced in virulence and were impaired in their ability to grow in the brains of newborn mice[24]. In contrast, the parental Dearing reovirus serotype 3, is highly neurovirulent ($LD_{50} \sim 10^1$) and grows to high titre in brain tissue. In fact, examination of brains of mice inoculated with these variants shows a tropism restricted to parts of the hippocampus (D. R. Spriggs, unpublished data). These observations indicate that when variants are selected for resistance to antibody directed at the major neutralization region of the viral haemagglutinin, viruses specifically attenuated for lethal central nervous system infection are generated. The most likely explanation for this type of attenuation is an altered interaction of the viral haemagglutinin with neurone receptors. In addition to being less neurovirulent, these variants show an altered interaction with cytolytic T lymphocytes[25]. Thus, either the identical site on the reovirus type 3 haemagglutinin protein is recognized by a neutralizing monoclonal antibody, cytolytic T lymphocytes and neurones, or the site(s) important for the last two interactions are close enough to that recognized by the antibody to be seriously affected by antibody binding.

Effect of antibodies against receptors that bind viral haemagglutinin. As suggested above, a decisive element in the successful interaction of the haemagglutinin with certain cells is a highly specific cell-associated receptor for the haemagglutinin. Because the receptor on lymphoid and neuronal cells is able to distinguish subtle differences in the structure of various haemagglutinins, it has been possible to develop a panel of xeno- and monoclonal antibodies to the viral receptor[26]. We reasoned that the antigen-binding site of antibodies that could interact with the neutralizing area of the haemagglutinin might resemble the binding site of the surface receptor on the neurone.

Table 2 Mutations attenuating reoviral virulence

Gene	Polypeptide	Function	Result of attenuating mutations	Ref.
S1	$\sigma 1$ (HA)	Binds to receptors: I nerve cells II lymphoid cells	Loss of neurovirulence Altered specificity in cytolytic T cell and humoral responses	24
M2	$\mu 1/\mu 1C$	I Growth at mucosal surfaces	Decreased capacity to grow at 1° site	28
		II Immune induction	Loss of immune stimulation of suppressor T lymphocytes	11
		III Growth in target tissue	Relative decrease in neurovirulence	26
S4	$\sigma 3$	Inhibition of RNA and protein synthesis	Persistent infection	16
			Interference	36
Multiple genes	Many proteins	Pleiotropic	Temperature-sensitive mutations have same tropism but reduced growth *in vitro* and *in vivo*	38

The fact that the same determinant recognizes the haemagglutinin suggests that the genetic basis of these binding structures on T lymphocytes or somatic cells (neurones) may involve a gene family similar to that which encodes immunoglobulin variable region products. Alternatively, we considered that limited conformational arrays necessary for HA-specific receptor construction might resemble the conformation of antigen-combining sites on antibodies having the same specificity[26].

BALB/c mice were inoculated with the BALB/c-derived monoclonal antibody (MC1) known to interact with the neutralizing region of the haemagglutinin. Spleen cells from these animals were fused to generate a second order panel of hybridomas, which were screened to isolate monoclonal antibody (MC2) potentially capable of interacting with the antigen-binding site of the first monoclonal antibody (John Noseworthy, unpublished). (Previously, we induced antibodies against anti-haemagglutinin by immunizing rabbits with anti-reovirus haemagglutinin antibodies[26].) These rabbit anti-anti-haemagglutinin antibodies have been used to mimic viral binding[27]. More recently, the MC2 antibodies have been found to limit binding of virus to appropriate targets (R. Kaufman, unpublished data). Thus, blocking viral receptors by MC2 prevents viral entry into susceptible cells and consequently the cells may be protected from infection.

The antibodies can also interact with lymphocytes in a manner analogous to the reovirus itself, as judged by the ability of such putative anti-receptor antibodies to activate subsets of T cells and to bind to a panel of cell lines which the virus binds[27]. We have observed, for example, that MC2 antibodies bind to cells which can interact with reovirus 3. This has been shown for various murine cell types and tumour cell lines of distinct H-2 types, as well as distinct heavy chain allotypes. The YAC (A strain, *H-2*^{a}) lymphoma line binds neither reovirus 3 nor MC2, but the R1.1 (C58, *H-2*^{k}) thymoma binds both reovirus and the MC2. Absorption of the MC2 with the R1.1 line also absorbs out the activity of MC2 binding to MC1, indicating that MC1-like viral receptors are present on the cell surface. This type of MC2 is not only of value in blocking binding of virus to cells but may be useful also *in vivo*, particularly against local surface infections. As the MC2 resembles a viral antigen, it might also be used to induce or augment immunity to viral diseases without exposure of the host to the virus. This strategy might be most advantageous in the development of an immunogenic 'vaccine', for protection against infection by more highly lethal viruses, for example, the agent responsible for rabies.

Another area of interest is the simple definition of an analogue of virus–receptor interactions by using two monoclonal antibodies, MC1 and MC2: MC1 resembles the receptor and MC2 mimics the virus. It is now possible to assess readily which of several tryptic peptides of the haemagglutinin is capable of inhibiting MC1–MC2 interaction. Those peptides which inhibit this interaction in a radioimmunoassay could probably generate immunity to the most relevant part of the viruses when administered *in vivo*. We predict that this principle (see Fig. 2) should also be applicable to other viruses and may allow the rapid screening and development of new vaccines (synthetic peptides, protein fragments, synthetic compounds). An alternative approach uses reovirus fixed to plates, and radiolabelled MC1 antibody. Tryptic or synthetic peptides of haemagglutinin can then be tested for their ability to inhibit the radiolabelled MC1 binding to the immobilized reovirus. Those peptides capable of inhibiting the interaction would be candidates for immunogens in vaccines. Again, the principle should also extend to other viral systems.

Attenuation via the μ1C protein

Effect of route of inoculation on virulence. The Dearing strain of reovirus serotype 3 is highly lethal when inoculated i.c. into suckling mice, a typical LD$_{50}$ being ~1 log$_{10}$ (ref. 16). However, when this strain is given orally, even in doses of 10^7 plaque-forming units (PFU) of purified virus, it is avirulent[28]. This quantity of type 3 reovirus fails to grow in intestinal tissue after it is deposited into the stomach of newborn mice and is inactivated when mixed with intestinal homogenates. In contrast, reovirus type 1 (Lang) strain inoculated by the same route multiplies in the intestine, then spreads to the brain where it produces a benign ependymitis similar to that which develops after intracerebal injection. Another difference between the two viruses is that the infectivity of the type 1 is unchanged or slightly enhanced by treatment with pancreatic protease chymotrypsin while that of the type 3 (Dearing) is dramatically decreased[28]. A genetic analysis using recombinant viruses generated between types 3 and 1 revealed that the ability to grow in intestinal tissue and the response to pancreatic proteases are properties of the M2 gene and hence the μ1/μ1C proteins[28], but is uncertain whether the two are causally linked.

Effect of variations of M2 on neurovirulence. In addition to determining growth in intestinal tissue, the *M2* gene plays a part in controlling the relative degree of neurovirulence of a natural isolate of serotype 3 (ref. 29). A large number of type 3 isolates were screened to ascertain their relative neurovirulence after i.c. inoculation. One strain retained the neurotropism of the type 3 (that is, infection of neurones but not ependyma) but was markedly less virulent (LD$_{50}$ of ~$10^{4.5}$ compared with type 3 Dearing LD$_{50}$ of ~10^1). Genetic analysis revealed that the attenuation in neurovirulence in this isolate was also related to its *M2* gene[29].

The results of these studies indicate that the nature of the *M2* gene (and μ1C polypeptide) is important in determining virulence after inoculation by the natural oral route and by the experimental intracerebral route. This effect seems to be mediated by how well reovirus grows either at the portal of entry or in the target central nervous system tissue. Thus, while tissue tropism is not affected by the *M2* genes, the ability of reovirus to grow and produce a lethal lytic infection is. The manipulation of the *M2* gene thus offers the possibility of attenuating reoviruses by reducing virus yield.

Induction of immunity. As indicated previously, the μ1C protein is normally sensitive to various proteases present in the

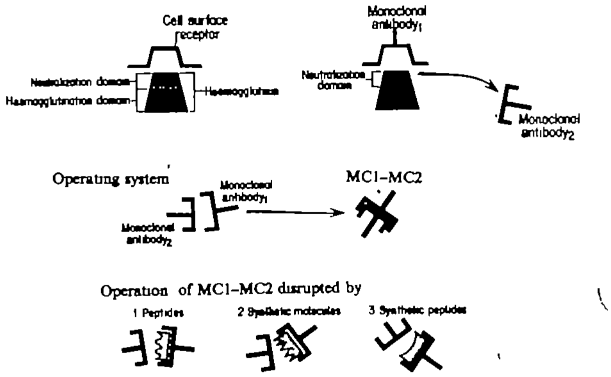

Fig. 2 Definition of an operational analogue of virus–cell receptor interactions. In the reovirus system, the neutralization domain of haemagglutinin interacts with cell surface receptors and the antigen-binding site of the monoclonal antibody (MC1) directed at that domain. A second monoclonal antibody (MC2) made against the antigen-binding site of the first interacts with the cell surface receptor for the neutralization domain, and also interacts with MC1. The MC2–MC1 interaction appears to be the analogue of the virus–cell receptor interaction and constitutes the operating system for studying proteins which can be used as potential immunogens. Only those proteins (or synthetic molecules) that interfere with MC1–MC2 binding are likely to be useful vaccines. In cases where the virus is not dangerous and easily purified, an alternative approach is possible: the virus is immobilized on polystyrene plates, and MC1 antibodies (directed against the domain of the virus that interacts with cell receptors) are radiolabelled and used to bind the immobilized virus. Any peptide or synthetic molecule which limits the binding of the radiolabelled MC1 to the virus is potentially useful as a vaccine. These systems could apply also to bacteria, fungi or parasites[34,35].

40 k

intestine[28]. However, oral administration of a virus having a mutant μ1C protein, resistant to intestinal enzymes, stimulated suppressor T cells (T_s) which abrogated the cellular immune response to the virus[11]. Thus, the μ1C polypeptide encoded by the *M2* gene plays a decisive part in the overall pattern of the immunological response when reovirus enters the host by the natural route. One possible explanation of these results is that a virus carrying μ1C that is resistant to enzymatic cleavage is processed in a manner which stimulates T_s activity. Evidence for special antigen-presenting cells in the generation of T_s has, in fact, recently been demonstrated (Adam Lowy, Jeffrey Drebin and M.I.G., unpublished results).

Attenuation via the σ3 protein

Effect of high passage on virus properties. Viral vaccines are often prepared by multiple passage of stock virus until attenuation occurs. The critical genetic lesions of most vaccine strains have not been identified. Many viral vaccines are partially temperature-sensitive (ts) suggesting that they may contain multiple mutations[30–32]. As the segmented genome of the reoviruses has allowed us to determine the locus of ts lesions, we investigated the nature of the ts and other lesions produced in reovirus types 1, 2 and 3 after serial, lytic passage[33]. Although scoring for every possible mutation was not feasible, several mutations were detected in these stocks, including ts mutants, deletions, cold-sensitive and non-ts interfering lesions. At several stages of passage, most of the ts and non-ts interfering mutants appeared in the tsG group, which has been found on the S4 gene encoding σ3 protein[34]. Thus, after repeated passage of reovirus in tissue culture performed in a manner analogous to generation of attenuated strains, the major mutations appear in the *S4* gene.

Defective interfering particles. Defective interfering (DI) particles are virus particles which lack a portion of the viral genome, contain normal structural proteins, require helper virus to replicate and interfere specifically with replication of homologous standard helper[35]. Reovirus DI particles are generated after serial passage of ts^+ or ts mutants in cell culture[36–38]. Reovirus DI particles often appear after several passages with ts^+ viral stocks, but may be detected earlier in stocks of ts mutants when passage is performed repeatedly. At high multiplicity of infection (MOI), the L1 dsRNA genome segment is most often lost, but deletion mutants lacking segments *L3* and *M1* have also been found. These replicate only in the presence of standard virus, and interfere with the growth of infectious reovirus.

DI viruses are highly attenuated. Because the precise mechanisms involved are unknown, the genetic interactions between reovirus DI and infectious virus were examined[39]; the results indicate that ts^+ recombinants form after crosses between reovirus DI particles and ts mutants or ts^+. We then asked whether DI particles contain other mutations, in addition to the deletion mutation. It was clear that ts and small plaque–low yield mutations are rescued from DI particles; both of these mutations were located on the *S4* gene segment. Indeed, some of the ts and attenuated viruses constructed from these crosses between DI particles and ts were able to interfere with the growth of wild-type reoviruses. Thus, like the repeated passage non-DI stocks, the more defective DI particle stocks were also highly enriched for viruses containing *S4* mutants.

Virus isolates from persistent infection. DI viruses are critical for the establishment of persistent infection in cell cultures[40]. By infecting L cells with DI stocks, a noncytocidal persistent infection can be established. To determine which gene(s) derived from the DI stock play(s) a critical part in the establishment of persistent infection, cells were co-infected with DI stocks and ts^+ virus[17]. If mutation in a particular gene is essential for the establishment of persistent infection, it should always be derived from the defective virus. Studies designed to examine this hypothesis indicated that the *S4* gene segment was always derived from the defective virus and was critical for attenuation in that it specifically produced non-lytic virus–cell interactions. Interestingly, a major role of the σ3 protein in the cell during lytic infection is to inhibit RNA and protein synthesis[18]. Mutant σ3 derived from persistently infected cells, has lost the capacity to do this. Thus, mutations in *S4* are attenuating because they are altered in their ability to lyse cells and inhibit synthesis of cellular protein and RNA. The *in vivo* significance of *S4* mutations has not yet been evaluated.

Temperature-sensitive mutations

That reovirus type 3 Dearing produces a lethal encephalitis after intracerebral inoculation has been discussed above. We have also pointed out that attenuation due to specific lesions in individual viral genes is often associated with viruses capable of full replication is cell cultures. In contrast to this specific type of attenuation, ts mutants whose lesions may be located in one of several viral genes are highly attenuated compared with parental wild-type virus[41]. Temperature-sensitive mutants are unable to replicate fully at relatively high temperatures such as the body temperature of the infected host. The extent of the attenuation associated with infection with ts viruses depends in part on the nature of the lesion. However, we now know the location of the lesions used in all our earlier studies and it is clear that attenuation of lethal encephalitis occurs with lesions in the reovirus core as well as with lesions in outer capsid proteins[42]. The attenuation is characterized by an intermediate level of destruction of neurones (that is, 'attenuation') that may be due to a virtually complete block in viral replication (ts C) or a block in replication at more intermediate levels (ts B)[41]. In no case have we found evidence of altered tropism with the reovirus ts mutants, although studies using vesicular stomatis indicate that this may occur[43].

Conclusions

For a virus or other microbial agent to produce infection in eukaryotic host it must enter through a major portal, spread (if it produces systemic disease) and ultimately find a distinct cell and tissue site. The host responds to the pathogen both at the portal of entry as well as systemically. Several stages of pathogenicity are common to all types of infectious agents, from the simplest viruses to complex parasites. Because viruses are the smallest and simplest of the infectious agents, they offer the possibility of establishing general principles that explain molecular mechanisms of microbial pathogenecity.

Several conclusions regarding features of attenuation of viral virulence and immunization emerge from this review. First, one viral component, the haemagglutinin, is responsible for determining cell and tissue tropism and is a major antigen for the humoral and cellular immune responses. Selection of viruses that are variant in critical regions of the haemagglutinin leads to attenuation. In addition, presumed anti-receptor antibodies generated against monoclonal antibodies directed against the binding site of the haemagglutinin, potentially can be used both to stimulate an immune response against the virus and possibly to block binding of virus at the level of the cell receptor. Such systems as those which we have defined by MC1 and MC2 monoclonal antibodies are analogues of the virus–cell receptor system and should permit the rapid *in vitro* screening of peptides, synthetic peptides and even synthetic compounds for use as vaccines.

Second, a viral component of the outer capsid, the μ1C protein, has a critical role in determining the ability of reovirus to replicate at the primary site in the gastrointestinal tract and the ultimate nature of the immune response. Thus, this component provides a second site on the surface of reovirus particles that can be altered, resulting in a reduced capacity of the virus to grow and interact with the host at portals of entry. Third, the σ3 outer capsid polypeptide, the component responsible for inhibiting synthesis of cellular RNA and protein, is the site of frequent mutations that decrease the capacity of reovirus to lyse cells. Such mutations often appear in viral stocks after they have been repeatedly passaged, and are present at high frequency in defective interfering particles. The presence of such S4 mutations is associated with attenuation in conditions where defective viruses are present.

Are other microorganisms similar to the mammalian reoviruses in the strategies they use in interacting with eukaryotic hosts during infection, and in the ways that the reoviruses can be attenuated? Although our conclusions are based largely on the results of studies using the reoviruses, it is possible that the lessons of the reoviruses will apply to other microorganisms. That different facets of viral virulence are properties of multiple viral genes has also been noted for the influenza viruses[4,44,45]. Despite the fact that virulence is multigenic and that multiple genes are involved in infection, individual viral genes are probably responsible for different facets of the process. For example, studies with a number of viruses including poliovirus[46], coxsackie virus[47], adenovirus[48], paramyxoviruses[49], and influenza virus[50], have emphasized that generally only one of the viral polypeptides is responsible for interacting with host receptors. While most of these investigations have described experiments using cell cultures rather than animal models, it is likely that similar results will be true *in vivo*. Note that, in most cases, it is the viral haemagglutinin that is the protein responsible for receptor interactions. The detailed mechanisms involving subsequent stages of viral infection involve different proteins and generally are not well understood. For example, influenza virus contains a second outer capsid protein, the neuraminidase, thought to have a role in allowing the virus to come into close contact with the target cell and possibly to aid release of virus from infected cells[51]. In addition, several viruses contain a fusion protein that is thought to participate in initiation of infection and expression of infectivity[52]. Clearly, discrete viral proteins, in addition to the haemagglutinin, are responsible for additional stages of infection.

With regard to aspects of the responses of hosts to viruses, an oligoclonal response as typified by the anti-haemagglutinin antibodies for reovirus can also be seen in the immune response to the influenza viral haemagglutinin. Studies by Liu *et al.*[53], for example, have clearly identified a variety of idiotypes against overlapping antigenic determinants on B/Lee haemagglutinin. They found both private as well as shared idiotypes and, in some cases, they detected totally cross-reactive idiotypes on monoclonal antibodies generated against a particular antigenic site. Recently, the effect of anti-idiotypic or anti-receptor reagents against other microorganisms have also been noted[54,55]. Such reagents may help to elucidate the binding structure for a variety of microbial agents and define new strategies of therapy for modulating microbial infection.

Thus, the increased understanding of the mechanisms of microbial pathogenesis that is based on model systems should provide important new approaches for the prevention and treatment of infectious diseases caused by diverse microorganisms.

Observations of reverse polarity flux transfer events at the Earth's dayside magnetopause

R. P. Rijnbeek, S. W. H. Cowley & D. J. Southwood

Blackett Laboratory, Imperial College, London SW7 2BZ, UK

C. T. Russell

Institute of Geophysics and Planetary Physics, University of California at Los Angeles, Los Angeles, California 90024, USA

Observations of flux transfer events (FTEs) at the Earth's dayside magnetopause are presented which have plasma and magnetic field signatures reversed in sign from those previously reported. These FTEs are interpreted in terms of localized and transitory reconnection with the spacecraft located south of the reconnection site. They are associated with a previously reported interval of quasi-steady reconnection which is similarly located, indicating that a close physical connection exists between the two processes.

0028–0836/82/440023—04$01 00

THE occurrence of large-scale plasma convection within the Earth's magnetosphere, driven by the external flow of the solar wind, has long been recognized as being of fundamental significance in determining the properties, structure and dynamics of magnetospheric plasma populations. There has, however, been much controversy concerning the nature of the physical processes which couple the magnetosphere to the external shocked solar wind (magnetosheath) and which initiate the convection cycle by transporting plasma and magnetic flux from the dayside boundary into the geomagnetic tail. The two main possibilities which have been discussed have been a 'viscous-like' interaction associated with wave–particle interactions and plasma diffusion at the magnetopause boundary[1,2], and magnetic reconnection, in which direct magnetic interconnection occurs between the solar wind and the magnetospheric flux tubes, resulting in these 'open' tubes being swept downstream into the tail by the magnetosheath flow[3]. These two types of processes may, however, coexist, and the determination of their relative importance in driving magnetospheric convection is a central problem in magnetospheric physics. Indirect evidence has supported the importance of reconnection but direct confirmatory observations have been lacking, due to the lack of data of sufficiently high time resolution from the dayside boundary regions.

Recently, high resolution plasma and magnetic field measurements made by the ISEE 1 and 2 spacecraft have become available, and have provided the first definitive observations of magnetic reconnection at the dayside boundary. These observations have shown that the reconnection can occur either as a large-scale, quasi-steady process enduring on time scales of at least a few tens of minutes[4–6] as originally envisaged by Dungey[3], or as a transient process, localized in both temporal and spatial extent. The latter form, termed the 'flux transfer event' (FTE), was first recognized by Russell and Elphic[7,8] from its characteristic magnetic signature in ISEE magnetosheath data, although apparently related field fluctuations inside the magnetopause boundary had previously been observed in low resolution HEOS 2 data, and described as possible 'flux erosion' events by Haerendel *et al.*[9]. The interpretation of such field phenomena in terms of localized reconnection has been supported by particle observations indicating that a mixture of magnetospheric and magnetosheath plasma occurs in FTE flux tubes both inside and outside the magnetopause[10–16].

Most of the flux transfer events discussed recently were those observed early in the ISEE 1–2 mission in November 1977 when the spacecraft encountered the magnetopause region on the dawn side of the Earth and at relatively high northern magnetic latitudes (20–40°). All of these encounters have been interpreted in terms of a spacecraft location northward of the reconnection region, such that the open FTE flux tubes which were observed were connected to the Northern Hemisphere of the Earth. The signatures associated with the passage of such a tube across the spacecraft may be readily envisaged with the aid of Fig. 1, following Russell and Elphic[7,8]. This diagram represents a view of the dayside magnetopause as observed from the magnetosheath, and shows the two 'ends' of a magnetosheath flux tube which has become connected across the magnetopause into the northerly directed (vertical) field of the Earth on the other side of the boundary as a result of a localized reconnection event. Due to magnetic tension, the reconnected flux tubes will contract along the magnetopause in the directions indicated by the broad arrows relative to the overlying magnetosheath plasma and field, causing perturbations in the latter as they do so, as illustrated. If we then consider the magnetic perturbations which should be observed by a spacecraft as the northern open tube passes across it, moving roughly in the direction of the broad arrow, then it is clear that the field will point outwards, away from the magnetopause as the open tube approaches, and inwards, towards the Earth as it recedes, while within the tube strong deflections of the field direction towards that of the Earth's field are expected. The overall plasma flow within the open tube should be deflected both to the north and to the west relative to the ambient magnetosheath flow due to the magnetic forces (the latter direction clearly depending on the sign of the east–west magnetosheath field component). This basic picture is quite consistent with previous FTE observations presented in refs 7, 8, 13 and 17. In particular all have shown the positive to negative signature of field perturbations directed along the outward normal to the magnetopause, and for those cases where a significant flow perturbation is observed it is directed northwards. Not all the FTEs show clear and consistent northward velocity perturbations however, making their identification as Northern Hemisphere open tubes rather less certain in these cases[16].

If we now consider the southerly tube in Fig. 1, again assumed moving roughly in the direction of its broad arrow, then the perturbations expected in both the magnetopause normal field component and in the plasma flow are reversed in sign relative to the northern tube, while deflections of the reconnected flux tube in the plane of the magnetopause should remain the same, that is northward towards the direction of the Earth's field[16]. We present here the first observations corresponding to this situation as observed by the ISEE spacecraft.

Observations

Our data were obtained by the ISEE 1 spacecraft during an inbound crossing of the magnetopause region on 9 August 1978 which occurred at a radial distance of $\sim 15 R_E$ and at a local time and magnetic latitude of ~1650 h and ~2° respectively. The spacecraft was thus located in the dusk local time sector and close to the magnetic equator. Plasma and magnetic field data for a 70-min interval spanning the magnetopause region are shown in Fig. 2. The plasma data were obtained by the Los Alamos/MPI fast plasma analyser and were taken from ref. 5, in which further details of the experiment may be found. Figure 2 shows the plasma density N_p (cm^{-3}) and flow speed in the equatorial plane V_p (km s^{-1}), both obtained at 12 s resolution, together with the GSM *z* (northward) component of the plasma velocity V_z (km s^{-1}) obtained at 48-s resolution. The magnetic field data were obtained from the UCLA fluxgate mag-

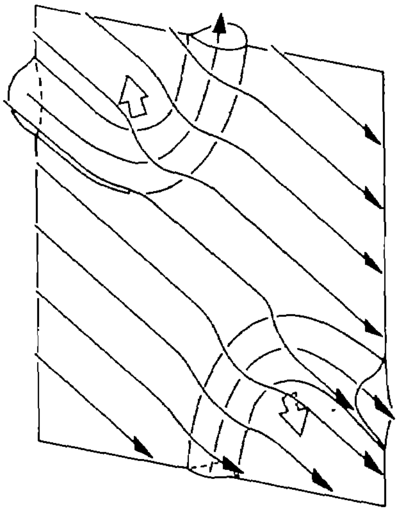

Fig. 1 Sketch of northern and southern 'ends' of open FTE flux tubes shown shortly after reconnection at the dayside magnetopause. The magnetic tension of the open tubes will result in their contraction along the magnetopause relative to overlying magnetosheath plasma and field in the directions indicated by the broad arrows. Consequently the open magnetosheath tubes will tend to tilt towards the direction of the Earth's field (northward) as shown, while the open magnetospheric (boundary layer) tubes will tend to tilt towards the magnetosheath field direction, both north and south of the reconnection site. Perturbations will also occur as shown in the overlying magnetosheath field, particularly in the field component normal to the magnetopause. If the net motion of the open tubes across a spacecraft is roughly as indicated by the broad arrows then the normal field perturbations will be outward followed by inward for the northern tube, and inward followed by outward for the southern tube.

netometer on ISEE 1 (ref. 18), and 12-s field averages plotted every 4 s are shown in boundary normal coordinates. In the latter system $\hat{N}$ is the estimated outward normal to the magnetopause at the spacecraft location and points duskward and sunward nearly in the equatorial plane. $\hat{L}$ is perpendicular to $\hat{N}$ and such that the L-N plane contains the GSM $\hat{z}$ axis; it is directed northward along the magnetopause. $\hat{M}$ completes the orthogonal system and points sunward and dawnward along the magnetopause. In Fig. 2 $\hat{N}$ was determined by assuming that to a sufficient approximation the magnetopause can be treated as a tangential discontinuity, in which the normal magnetic field component threading the current sheet is taken to be zero. The $\hat{N}$ direction is then given by the cross product of representative field vectors on either side of the boundary, from which its GSM components were found to be (0.753, 0.644, 0.139). This procedure does not really conflict with the possibility that the magnetopause is magnetically open during this traversal as the strength of the normal field is generally expected to be around an order of magnitude less than that of the tangential components. Note also that the above normal is in reasonable agreement with the Fairfield[19] model magnetopause normal for the spacecraft location and also does not differ significantly for our purposes from the minimum variance normal employed by Sonnerup *et al.*[5]. The angle between the Fairfield normal and Sonnerup *et al.* normal and that used here is ~14° in both cases.

The basic features of the 9 August 1978 magnetopause passage may be readily discerned from the plasma and field parameters displayed in Fig. 2. Initially the spacecraft is located in the magnetosheath as can be seen from the high plasma density and bulk speed, and from the southward and duskward (tailward) field directions (that is, B_L and B_M are both negative). There then follows an interval from 1934 to 1953 UT which is interpreted by Sonnerup *et al.*[5] as a partial penetration of the magnetopause/boundary layer region. The magnetosheath is then re-entered, until at 2011 UT a final crossing of the magnetopause occurs after which the magnetic field takes on its northward and sunward (dawnward) magnetospheric direction (that is B_L and B_M are both positive). Inside the magnetosphere after the final magnetopause crossing several pulses of flowing boundary layer plasma also occur.

From a detailed examination of the plasma, energetic particle and magnetic field data Sonnerup *et al.*[5] were able to deduce that quasi-steady reconnection was taking place in the vicinity of the spacecraft during this magnetopause passage. In particular it was inferred that the magnetopause/boundary layer region observed between 1934 and 1953 UT was located on open magnetic field lines southward of the reconnection region. In Fig. 2 this is indicated by the substantial increases of plasma flow speed observed during this interval, and the southward deflection of its direction. These changes in the plasma flow were shown to be quantitatively consistent with the requirements of tangential stress balance across an open magnetopause with B_N positive (that is, on open tubes connected to the Southern Hemisphere of the Earth). The tangential magnetic field during the 1934 to 1953 UT interval is seen to be intermediate in direction between magnetosheath and final magnetospheric values, that is it is directed predominantly northward and tailward. In the terminology of Hones *et al.*[20] this corresponds to an example of 'reverse draping' of the boundary layer field (that is tailward field tilts north of the Equator) on the dusk side of the magnetosphere. In this case, however, the direction of the boundary layer field tilt clearly relates to the direction of the field in the magnetosheath (where B_M is negative) and is just that expected for open tubes being pulled tailward from a reconnection site north of the spacecraft[21]. This observation may help explain the unusually lengthy nature of this apparent 'magnetopause' encounter.

The main feature of the data to which we wish to draw attention here, however, is the occurrence of two prominent FTEs which occur on either side of the quasi-steady open boundary layer region described above. These can be seen in Fig. 2 at ~1921 and ~2004 UT and they display all the classic FTE properties described by Russell and Elphic[7,8] and Paschmann *et al.*[13] (their category C), except for the negative to positive polarity of the B_N signature and the small but clear southward deflections of the magnetosheath plasma flow. These properties are the reverse from those reported for such events in the literature so far. Properties which remain the same as those previously reported include the following:

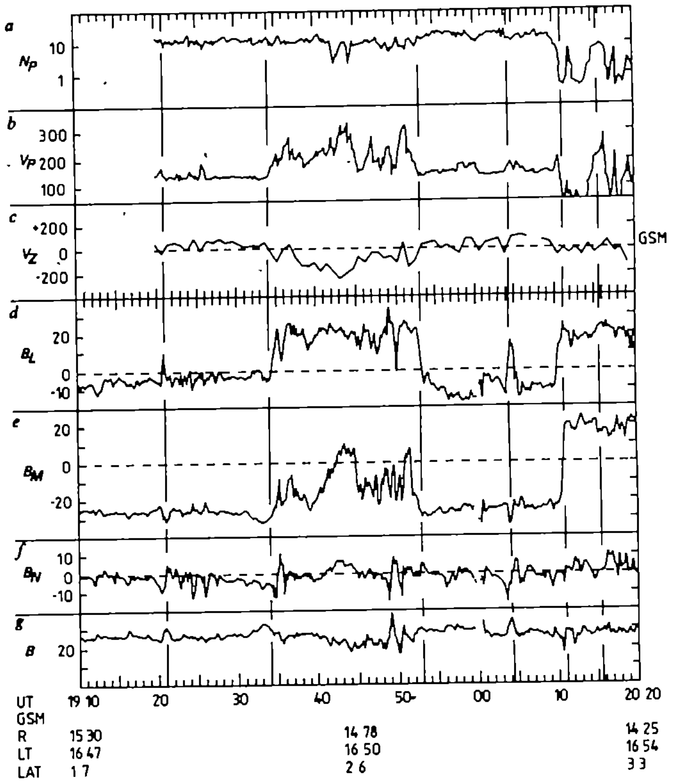

Fig. 2 Plasma and magnetic field data spanning the magnetopause boundary region obtained by ISEE 1 on 9 August 1978. *a–c* Plasma data obtained by the Los Alamos/MPI fast plasma analyser and published by Sonnerup *et al.*[5]. *a* and *b* show the plasma density N_p (cm^{-3}) and equatorial plane bulk speed V_p(km s^{-1}) respectively, both obtained at 12 s resolution while *c* shows the GSM *z* (northward) component of the plasma velocity V_z (km s^{-1}) obtained at 48 s resolution. The magnetic field data in *d–g* are 12 s averages plotted every 4 s and shown in boundary normal coordinates. A ~1 min gap in the ISEE 1 magnetic field data centred on ~2000 UT has been filled by ISEE 2 data in the figure, as indicated by the small dotted interval. Note that the ISEE 1 and 2 field data are essentially identical throughout this traversal, due to a small spacecraft separation. The separation vector in *L*, *M*, *N*, coordinates from ISEE 1 to ISEE 2 was ~45, 80, 65 km. The flux transfer events can be seen at ~1921 and ~2004 UT.

(1) The direction of the tangential field is deflected strongly towards that of the Earth's field as indicated by the changes in both B_L and B_M components (the latter satisfying $\Delta B_M/B_M > 0$).

(2) Both the magnetic pressure and the plasma pressure (see ref. 5) are considerably enhanced during the events.

(3) The events occur for southward directed magnetosheath fields ($B_L < 0$).

These properties are clearly those anticipated above for the propagation of localized reconnected FTE flux tubes across the spacecraft which are located south of the reconnection line and connected to the Southern Hemisphere of the Earth.

Note that the negative to positive B_N perturbations in these FTEs extend well outside the interval in which the open tube itself is observed, the latter interval being defined by the sharp northward tilt of the field in the plane of the magnetopause. These extended B_N perturbations result from the distortion of the magnetosheath field overlying the open tube as depicted in Fig. 1, and tend to maximize near the open tube boundaries as expected. Figure 2, however, shows that B_N perturbations are also present within the open tube itself as previously noted for 'normal' polaritiy FTEs[13,16]. The appearance of these B_N fields suggests that the open field lines are twisted about the axis of the FTE flux tube, associated with the presence of a distributed field aligned current (FAC) which is flowing along it. The direction of current flow in the present case is deduced to be parallel to the magnetic field from magnetosphere to magnetosheath, compatible with the direction of low-altitude 'region 1' currents in the dusk sector. Similar conclusions apply to previously published 'normal' polarity FTEs in the dawn sector which again show current flow parallel to the magnetic field, but now directed from magnetosheath to magnetosphere as the tubes are connected to the Northern Hemisphere of the Earth[16]. In all these cases the sense of the B_N perturbations observed inside the open tube is the same as those occurring outside the open tube which arise from the distortion of the overlying magnetosheath field, thus resulting in a simple overall bipolar B_N signature. In some circumstances the senses of the B_N perturbations arising from these two sources may differ, so that more complex FTE B_N behaviour may then be anticipated.

Note that in principle a 'reverse' negative to positive B_N FTE signature arising from distortion of the overlying magnetosheath field could also be produced at dusk by the northern tube shown in Fig. 1. This could occur when the tailward-directed magnetosheath flow becomes sufficiently rapid near the magnetospheric flanks that such an open tube can be carried predominantly tailward by the flow against the direction indicated by the magnetic tension (the broad arrow in Fig. 1). This is unlikely to be the case at the ISEE location in Fig. 2 as the magnetosheath flow speed and the Alfvén speed are comparable in magnitude (~150 km s^{-1}). One could then expect to observe a reduction, if not a reversal in the equatorial plane flow, together with a northward deflection in its direction. The observed variations of the flow do not show such behaviour, but rather are in the opposite direction. We therefore feel that the observations indicate that the 'reverse polarity' FTE events which occur at ~1921 and ~2004 UT in Fig. 2 are connected to the Southern Hemisphere. This conclusion has been confirmed by examination of energetic (>45 keV) ion data, which show that both FTEs are associated with enhanced fluxes of ions, inferred to be of magnetospheric origin, streaming parallel to the field from the magnetosphere into the magnetosheath. (P. W. Daly, personal communication).

Finally note that magnetic field and plasma fluctuations which seem to be closely related to the above FTEs can be seen in Fig. 2 in the interval ~1922–1928 UT following the first clear FTE, as the spacecraft enters the magnetopause region at ~1935 UT, within the latter region at ~1949 UT and in the second magnetosheath interval at ~2000 UT. Other events were also observed before and after the interval displayed. In addition, the large pulse of accelerated boundary layer plasma observed at ~2015 UT after the final magnetopause crossing appears to be associated with a 'reverse polarity' negative to positive perturbation in B_N, together with a ~20° tailward tilt of the boundary layer field lines towards the direction of the magnetosheath field relative to adjacent magnetospheric field directions. This behaviour of the boundary layer field corresponds to that expected for a magnetospheric open FTE flux tube reconnected north of the spacecraft, although the large general level of magnetic fluctuations occurring in the magnetospheric boundary in Fig. 2 makes this identification uncertain. The interpretation of pulse-like boundary layer encounters such as this in terms of magnetospheric FTEs has been dicussed previously in refs 12, 13, 16 and 22.

Discussion and conclusions

From an analysis of ISEE 1 plasma and magnetic field data Sonnerup *et al.*[5] have shown that quasi-steady reconnection was occurring at the dusk magnetopause during an inbound crossing of the boundary region on 9 August 1978. They showed that the spacecraft was located south of the reconnection region at this time, the only such example found in the 11 reconnection events studied by the above authors. This example was also the most southerly located of these events, being only ~2° N of the magnetic equator compared with ~20° to ~40° N typical of the other encounters. We have shown that both before and after the ISEE encounter with the quasi-steady open boundary layer region studied by Sonnerup *et al.*[5] impulsive reconnection was occurring at the magnetopause as evidenced by the observation of flux transfer events in the plasma and magnetic field data. The signatures of these FTEs differ from those previously reported, however, in that the polarity of the B_N field perturbations is from negative to positive rather than vice versa. This, taken together with the small but clear southward deflections of the plasma flow observed during the events and the energetic ions flowing parallel to the field strongly indicates that these open FTE flux tubes were, like the quasi-steady open boundary layer flux tubes, located south of the reconnection region and hence connected to the Southern Hemisphere of the Earth at this time. As regards the actual position of the reconnection region little can be said at present other than that essentially all the available evidence points towards a roughly equatorial location, possibly tilting north–south away from the subsolar region in response to the IMF B_y component (see for example, refs 23–26) to accommodate results such as the above.

It is significant that FTEs with the above characteristics indicative of connection to the Southern Hemisphere should appear in close association with observations of a quasi-steady open boundary layer region which is inferred to be similarly connected. This association strongly suggests that a close link exists between the two observed reconnection phenomena. At least one other quasi-steady reconnection event is also known to be associated with the appearance of a magnetosheath FTE during the crossing of the boundary region[5,13]. This case was observed on 11 September 1979 near local noon at ~22° north magnetic latitude, and is consistent with the reconnection processes being located south of the spacecraft at that time.

It will be interesting to examine other quasi-steady reconnection events for the presence of associated FTEs. The observations reported here indicate that during the spacecraft penetration of the boundary region the reconnection which was occurring evolved from being unsteady to steady and back again in the local time sector sampled. Whether this represents a basically temporal sequence or rather a spatial pattern which moves into and then out of the spacecraft vicinity remains unclear.

This work was performed while S.W.H.C. was supported by an SERC advanced fellowship, while R.P.R. was supported by a SERC studentship. Work at UCLA was supported by NASA under contract NAS-5-25772.

Environmental radioactivity in Cumbria

D. H. Peirson, R. S. Cambray, P. A. Cawse, J. D. Eakins & N. J. Pattenden

Environmental and Medical Sciences Division, AERE Harwell, Oxon OX11 0RA, UK

The distribution of radioactivity discharged from Sellafield in Cumbria (north-west England) has been measured against a background of nuclear weapon fallout, with the object of determining the pathways and transfer mechanisms between various environmental media.

THE natural radioactivity in the environment arises primarily from uranium and thorium, including the series of decay products, and from potassium. Nowadays, the naturally occurring radioactivity is overlain by artificial radioactivity deposited with the debris from more than 30 yr of nuclear weapon testing. Most of this material, having been injected into the stratosphere, is deposited on a global scale according to a recognized latitudinal pattern[1].

Possible emissions by the nuclear power industry, from reactors or processing plants, will have constituents similar to the radioactivity of the nuclear weapon fallout, namely a mixture of the transuranic elements, fission products and nuclides in gaseous form such as tritium and ^{14}C. To distinguish the emissions from the fallout it would be necessary to measure the former against baselines set by the latter. As an indication of the scale of the effect of nuclear weapon tests, about 500 Ci of Pu had been deposited in the United Kingdom by 1980[2]: the current contribution of the external radiation from deposited weapon fallout (mainly ^{137}Cs) amounts to about 3% of the natural background[2]. Radionuclides from weapon tests have been measured continuously for nearly three decades: the cumulative deposition has been assessed directly in a more recent programme of soil sampling throughout Britain. Figure 1 shows the deposition countrywide of ^{137}Cs from nuclear weapon fallout up to 1977 plotted in contour form[3].

To investigate the environment of the Sellafield (Windscale) establishment in Cumbria (north-west England), it is necessary first to measure the distribution of radioactivity in various environmental media. Then it would be possible to study the mechanisms of transfer between these media, for example, between sea and land, within soil and between soil and plants. Because the amounts of radioactivity are so low the sensitivity of measurement of the radionuclides must be much greater than that required for monitoring according to the normal radiological limits. Artificial radioactivity in Cumbria will arise from: fallout from nuclear weapon testing; discharge to air from the Sellafield works; and discharge to sea from the Sellafield pipelines.

Table 1 Cumulative deposition of ^{137}Cs and Pu in Cumbria grassland (1978)

	Locality	Average annual rain (mm)	Deposition (pCi cm^{-2}) ^{137}Cs (0–15 cm)	^{137}Cs (0–30 cm)	$^{239+240}$Pu (0–15 cm)	^{238}Pu (0–15 cm)	Ratio ^{137}Cs/$^{239+240}$Pu (0–15 cm)

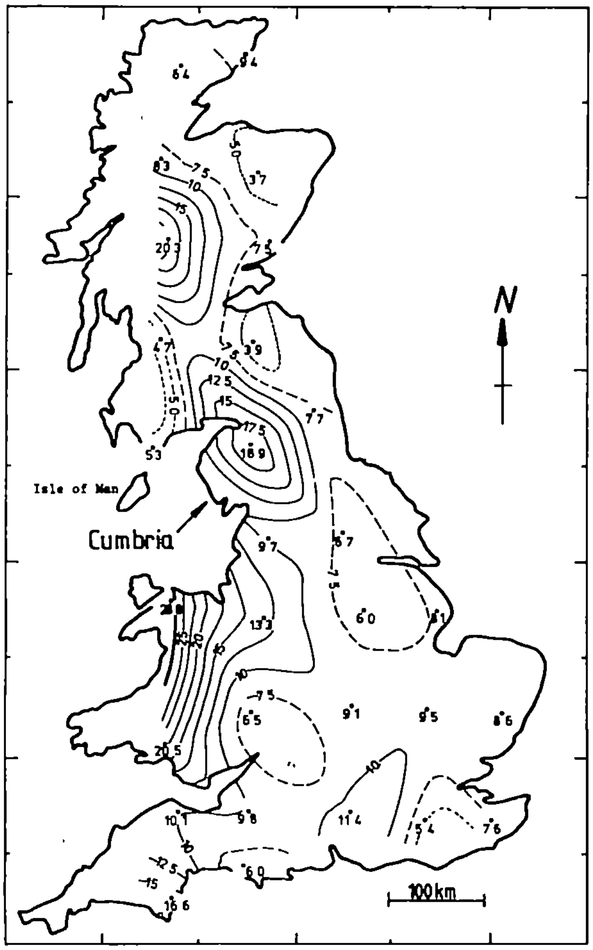

Fig. 1 Cumulative deposition of ^{137}Cs to grassland in Britain (1977). pCi cm^{-2} to 30 cm depth.

The radioactivity discharged by 1978 from Sellafield into the Irish Sea includes more than 12 kCi of Pu α activity and 600 kCi of ^{137}Cs (see ref. 4).

The investigation described here fell into three parts: (1) a survey of radioactive deposits accumulated in soil throughout Cumbria—an intensification of the larger scale survey of Britain; (2) a more detailed survey of soil along the coastal region, together with transects running inland from the coast; (3) measurement of current levels of radionuclides in air and rain.

Cumbria soil survey

The area of some 2,500 km^2 in Cumbria[5] (and the Isle of Man) was covered by a network of sampling sites based on a grid of 10 km side. Soils were sampled in 1978 to a depth of 30 cm from permanent grassland and woodland. Sites were selected on undisturbed land, that was likely to remain undisturbed to allow repetitive sampling in the future and with no history of flooding.

Samples of soil were taken with a corer of diameter 3.8 cm. At each site at least 10 cores were taken at random at both 0–15 cm and 15–30 cm depth and included the grass and root-mat layer. The cores were bulked to provide composite samples for each depth. The composite samples were air dried (at room temperature) and ground to $<150\ \mu$m, including stones and roots. About 100 g of soil were analysed for ^{137}Cs and Pu. The content of ^{137}Cs was determined by γ-ray spectrometry using a Ge–Li detector. Plutonium was leached from the soil by a 5:1 mixture of HNO_3/HF using ^{242}Pu as an internal tracer. $^{239+240}$Pu and ^{238}Pu were separated from the leachate and analysed by α spectrometry.

The accumulated depositions of ^{137}Cs and Pu are listed in Table 1 in terms of radioactivity per unit area of ground surface. As mentioned previously these deposits include a contribution from nuclear weapon fallout: the measured deposit relative to weapon fallout is shown in Fig. 2 for the two radionuclides, by converting the results of Table 1 as follows. Average deposition (0–15 cm) from weapon fallout in Britain as determined by the countrywide soil survey is 7.5 pCi cm^{-2} for ^{137}Cs and 0.14 pCi cm^{-2} for $^{239+240}$Pu (ref. 3), both normalized to 1,000 mm annual rainfall. (The coefficients of variation are respectively 50 and 25% for 58 sites.) The characteristic ratio in deposition of these radionuclides in 1977 is therefore about 54. Normalization to annual rainfall rests on the effective proportionality between weapon fallout and rain demonstrated in the countrywide survey[3], and on earlier work[6]. The average rainfall for the period 1941–70 was extracted from an index[7] of the rainfall stations nearest to the soil sampling sites. The relative deposition is then given by the ratio of the observed deposit to the nuclear weapon deposit scaled to the mean annual rainfall at the sampling site. Contours of relative rather than absolute deposition are mapped for ease of presentation. The finer structure exhibited by more intensive sampling is not shown. There are uncertainties in the derivation of the relative deposition values, associated with the interpolation between raingauge stations, retention of ^{137}Cs and Pu in the top 15 cm of soil and normal variability in sampling and analysis. Hence only values of relative deposition in excess of 1.5 are considered to be significantly greater than weapon fallout.

Figure 2*a* shows that the deposition of ^{137}Cs is concentrated near the coast and decreases fairly rapidly inland where the levels are indistinguishable from those due to weapon fallout. The major pattern located around Sellafield represents an accumulation of ^{137}Cs released presumably by aerial emission. To the south-east a smaller peak can be attributed to ^{137}Cs that escaped in the Windscale accident of 1957 (ref. 8). The results for each site (Table 1, Fig. 2) are compounded from the analysis of 10 cores. The relative deposition at site no. 6 of ^{137}Cs is consistent with the results of the Bootle transect[9].

Figure 2*b* shows that the contours of relative deposition of $^{239+240}$Pu are similarly concentrated around Sellafield, with the hinterland mainly free of excess radioactivity. However, there is no anomaly to the south-east, confirming the absence of measurable amounts of this radionuclide from the emission during the accident in 1957. Another difference from the ^{137}Cs pattern is indicated by the slight enhancement along the coast remote from Sellafield, suggesting that $^{239+240}$Pu has arrived from the seaward direction. This indication is supported by the values of the ratio ^{137}Cs/$^{239+240}$Pu (Table 1), measured at sampling sites near the coast, that are appreciably lower than the values for the hinterland (which are characteristic of weapon fallout). This implies that there is a relative excess of $^{239+240}$Pu along the coast not only in the vicinity of Sellafield but also in the more distant parts. In the Isle of Man no significant deposits in soil of ^{137}Cs and $^{239+240}$Pu were found in excess of weapon fallout[5], because presumably of the greater distance from the point of discharge to the sea.

It is possible to integrate the various depositions to grassland soils in Cumbria over the study area as defined by Fig. 2. Thus the excess of $^{239+240}$Pu (to 15 cm depth) due to the Sellafield operation is 2.4 Ci against a background due to weapon fallout of 5.9 Ci: the corresponding estimates for ^{137}Cs are 54 Ci against 315 Ci. The uncertainty of these integrals is probably less than a factor of two.

The radiological implications of these radionuclides in soil may be assessed by considering the potential for resuspension—by wind or other mechanical disturbance—and subsequent inhalation by man. The uppermost layers would be involved in resuspension, whereas most of the deposition over years will have penetrated more deeply into the soil. Calculations of this type have shown that the highest concentrations observed in soil in Cumbria are a very small fraction of the 'derived limit'[5] and hence constitute an insignificant hazard. This limit is derived from the limits set by the International Commission on Radiological Protection for the protection of the general public.

Table 2 Radionuclides in airborne and deposited material (November 1978–October 1979)

	Ratio of coastal station to weapon fallout			Ratio of coastal to inland station			Nuclear* weapon fallout
	St Bees	Eskmeals	Walney	St Bees	Eskmeals	Walney	
Air							(10^{-18}Ci kg^{-1})
^{137}Cs	9.2	4.9	3.3	0.9	0.8	1.2	240
$^{239+240}$Pu	12	19	4.0	1.8	2.7	1.9	6
^{241}Am	80	190	30	1.6	9	2.0	0.2
Na (stable)	—	—	—	2.5	1.9	1.3	—
Deposit							(10^{-15}Ci cm^{-2})
^{137}Cs	10.7	8.9	4.7	2.5	2.0	1.0	36
$^{239+240}$Pu	120	240	56	7.1	14	4.6	0.4
^{241}Am	1,000	1,600	600	10	16	6	0.019

* As observed at Milford Haven[14].

Coastal survey and transects

As well as the comprehensive survey of Cumbrian soil, a more rapid and detailed study was made of the coastal region together with transects running inland from the coast. The coastal and transect surveys[9] were designed to give an early indication of any radioactive anomalies and also to discover any effect due to the radioactivity discharged from Sellafield into the Irish Sea.

The sampling method was similar to that described above except that the samples were restricted to the top 15 cm of soil. Samples were taken from grassy sites, generally ~2 km apart, from roadside verges, edges of fields and open moorland between December 1977 and March 1978. Six transects were selected, starting at points on the coast between 10 km north (St Bees) and 30 km south (Kirkby) of Sellafield. The transects extended inland to 20 km: samples were collected at various times between 1977 and 1979. The samples were analysed for ^{137}Cs and Pu isotopes by methods described above: a limited number were also analysed for ^{241}Am.

The results from the 45 central sites in the coastal survey are shown in Fig. 3, together with the ratios ^{137}Cs/$^{239+240}$Pu and ^{238}Pu/$^{239+240}$Pu. The weapon fallout baselines for each parameter are shown as straight lines, because the rainfall is effectively uniform over the coastal region.

Figure 3 shows that there are significant departures from the baseline for all parameters. All sites between 13 km north and 27 km south of Sellafield have excess $^{239+240}$Pu over the baseline value (that is >1.5 times). The highest value is 70 times and there are some anomalous values at greater distances. The value

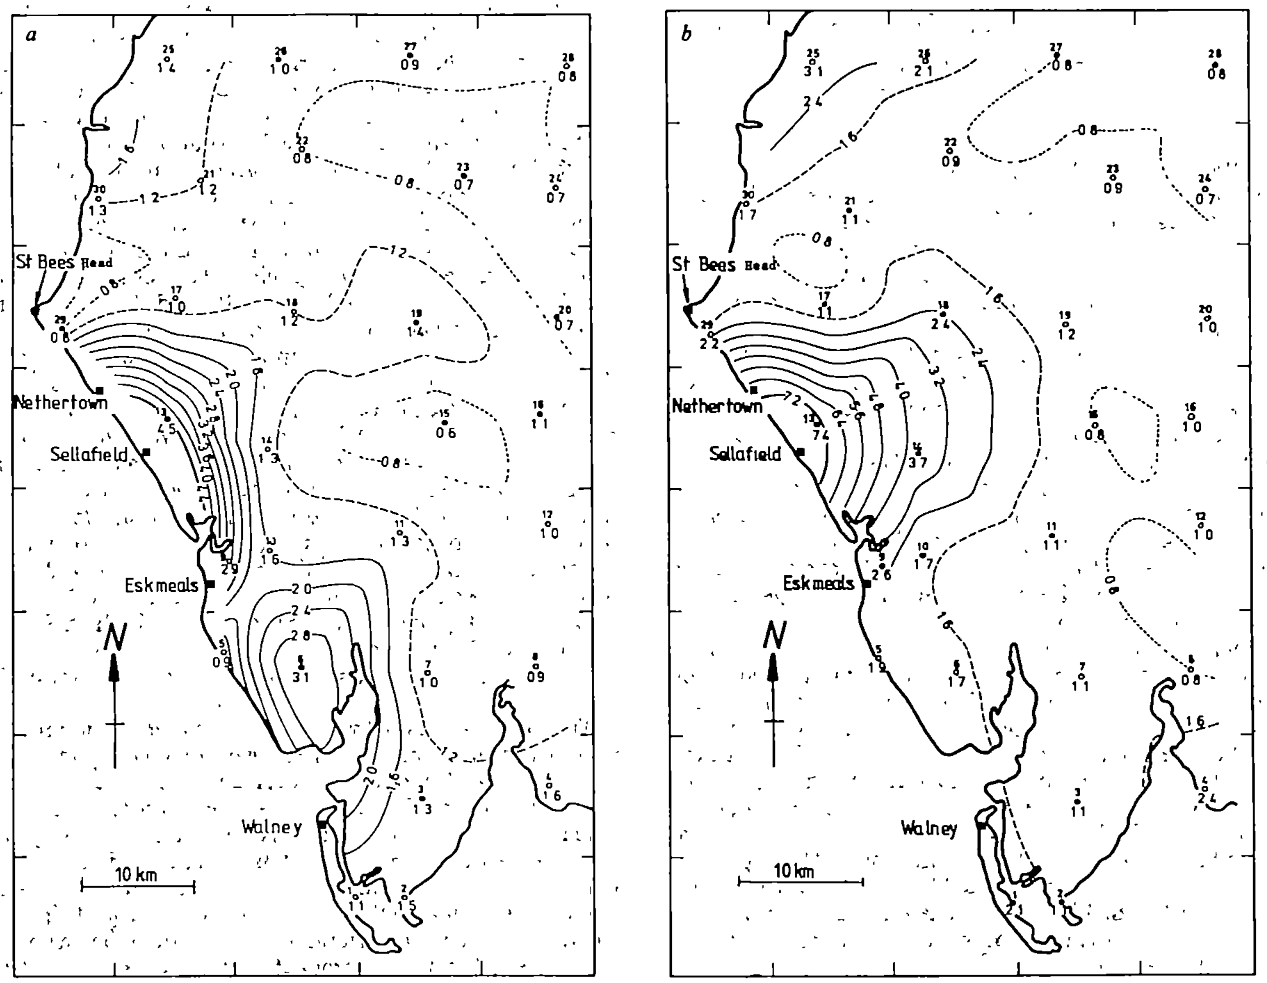

Fig. 2 Cumulative deposition of *a*, ^{137}Cs; *b*, $^{239+240}$Pu in Cumbria grassland (1978) relative to nuclear weapon fallout: 0–15 cm depth. Upper number is site identifier.

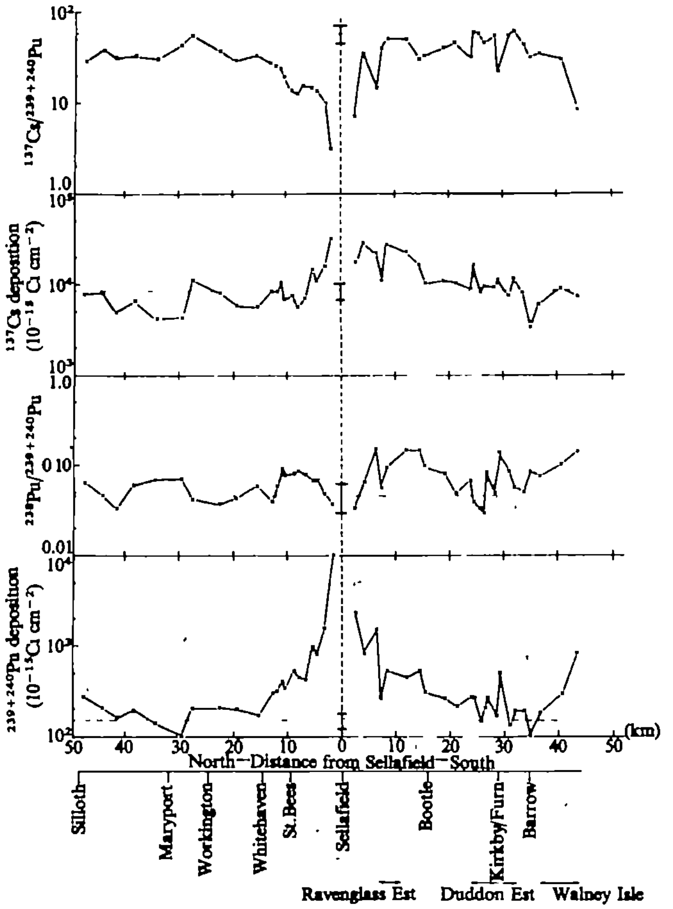

Fig. 3 Cumulative deposition of plutonium and ^{137}Cs in coastal soil of Cumbria (1977–78): 0–15 cm depth. – – –, Weapon fallout baseline.

of the ratio $^{238}Pu/^{239+240}Pu$ is elevated over the central region except close to Sellafield where it is depressed below the baseline. The deposition of ^{137}Cs does not exceed the baseline by as much as does Pu, in fact throughout the survey the ratio $^{137}Cs/^{239+240}Pu$ tends to lie below the baseline. However, the asymmetry of both radionuclides, with more to the south, is greater for ^{137}Cs.

The transect measurements show enhanced values of $^{239+240}Pu$ at the coast, between 3 and 11 times the weapon fallout baseline[9,10]. These fall to the baseline value at ~5 km and further inland, and the ratio $^{238}Pu/^{239+240}Pu$ is increased within 5 km of the sea above the value 0.05 which is characteristic of weapon fallout[11]. On the other hand there is no marked enhancement in the deposition of ^{137}Cs along the transects.

The patterns displayed by the coastal and transect surveys may be interpreted as follows. The excess ^{137}Cs can be explained by routine atmospheric discharges from Sellafield, together with the accident in 1957. Some of the excess local plutonium can be attributed to atmospheric discharges but it is difficult to use this source to account for the more remote coastal deposition (in excess of weapon fallout) and in particular for the regular decrease along the transects with increasing distance from the coast. These features suggest a contribution of Pu, but little ^{137}Cs, from the seaward direction. This contribution is marked by an enhanced value for the ratio $^{238}Pu/^{239+240}Pu$ approaching the value of ~0.3, characteristic of Sellafield discharges[12], at the coast but merging into the baseline value, of 0.05 due to weapon fallout[11], at ~5 km inland. The reduced values of this ratio close to Sellafield can be related to early atmospheric discharges[13] after short times of irradiation of the fuel, that is before substantial build-up of ^{238}Pu.

A two-dimensional summation of accumulated radionuclides may be based on the coastal and transect results, but neglecting the data from sites within 3 km of Sellafield: these were probably affected by direct atmospheric discharges. This rough estimate suggests that 1–2 Ci of excess Pu has been deposited in a coastal strip about 5 km wide and 40 km long. The deposit represents 10^{-4} of the quantity discharged to sea[4].

Airborne and deposited material

So far we have concentrated on an investigation of the cumulative deposition of radionuclides in soil. The coastal survey had shown anomalous accumulation at sites some distance from Sellafield: a complementary series of measurements was made of the current levels of radionuclides in air and rain. Six stations were established in the Cumbrian coastal region, deployed as three pairs, one of a pair on the coast and the other several kilometres inland. The coastal stations were sited at St Bees Head, Eskmeals and Walney (Fig. 2), where an excess of cumulative plutonium had been demonstrated (Fig. 3).

Airborne particulate was sampled continuously at a height of 1 m above ground by passing air through polystyrene filters at the rate of ~75 tonnes per month. Deposited material (wet or dry) was collected in a plastic bottle (25 l), containing tracer and carrier solution, through a funnel of 40 cm diameter. The monthly samples of airborne dust on filters and of rainwater (after evaporation and including the insoluble material) were analysed by γ-ray spectrometry followed by radiochemical methods, whereby Pu and Am were separated, using ^{242}Pu and ^{243}Am as internal tracers, and measured by α spectrometry. Stable trace elements were determined, as appropriate, usually by neutron activation analysis.

The results of these measurements in terms of the annual mean values and monthly ranges for the period November 1978 to October 1979 are reported in detail elsewhere[14] and are available for several radionuclides (actinides and fission products) and stable elements. For the present purpose the data are compressed into Table 2 which is restricted to the results for a few radionuclides and one stable element. These results of concentrations in airborne or deposited material are expressed as ratios to (1) contemporary values of weapon fallout observed at the long-established station at Milford Haven (distance 320 km) and (2) those from the corresponding inland stations. The information in Table 2 demonstrates: (1) an excess of radionuclides compared with nuclear weapon fallout; (2) an excess at the coast compared with inland (except for ^{137}Cs in air); (3) a greater excess for actinides than for fission products (particularly for deposited material); and (4) an apparent difference in the behaviour of airborne and deposited material.

The excess over nuclear weapon fallout is most marked for the actinides in deposited material (Table 2). Most of the additional ^{137}Cs can be explained by contributions from the discharges to air at Sellafield and from seawater that is suspended as spray[14]. In the case of actinides the same explanation cannot apply. Most of the actinides come from the seaward direction but if there is an association with suspended seaspray then a large enrichment over normal seawater is required[14], by a mechanism that is under investigation. This required enrichment is indicated by the ratios of the radionuclides to sodium compared with those in bulk seawater from the Irish Sea. The station at St Bees Head is 100 m above sea level and is likely to sample other forms of spray than the other coastal stations at sea level.

The discrepancies between airborne and deposited material in respect of the comparisons with weapon fallout and between coast and inland suggest an instrumental effect due to particle size, based on the postulate that a much larger fraction of the actinides than fission products is carried by relatively large airborne particles. This is qualitatively in accordance with the inference above that the main source of Pu and ^{241}Am is suspension of material coming from the seaward direction, whereas the major contribution to ^{137}Cs (together with ^{134}Cs and some other fission products) comes from the Sellafield discharges to air. In some investigations sea-spray and sand particles have been observed airborne with diameters of 100 μm or greater[15,16]. The sampler used for collecting airborne particulate, like all similar equipment, has a reduced efficiency in field conditions for collecting particles above ~20 μm diameter especially in lateral winds of high speed. The same limitation does not apply to the deposition sampler: this explains the discrepancy between the results obtained for airborne and deposited material exhibited in Table 2.

The potential radiological hazard from airborne radioactivity may be estimated by calculating the derived air concentrations for inhalation of $^{239+240}$Pu, which is the critical radionuclide. (The 'derived air concentration' may be defined by analogy with the definition of the derived limit.) The highest annual average concentration observed was 93×10^{-18}Ci kg^{-1} of air at Eskmeals, representing 0.2% of the derived air concentration[14], modified for the public.

Sea to land transfer

In the general soil survey of Cumbria it was shown (Fig. 2*b*) that there was a slight but significant enhancement of $^{239+240}$Pu in coastal regions remote from Sellafield. This indication is supported by the values (Table 1) of ^{137}Cs/$^{239+240}$Pu. The ratio is appreciably lower at the coast than that inland, which is characteristic of weapon fallout. This implies an excess of $^{239+240}$Pu at the coast and is consistent with a source of the excess lying in a seaward direction. Along the transects running inland the concentration of $^{239+240}$Pu was enhanced at the coast and decreased with increasing distance from the coast[9,10]. This feature suggests a significant contribution of $^{239+240}$Pu (and ^{241}Am) but not ^{137}Cs from the sea: the excess is characterized by values at the coast of the ratio ^{238}Pu/$^{239+240}$Pu that are higher than the baseline due to nuclear weapon fallout and nearer to that of the Sellafield discharges to sea[12]. For the airborne and deposited material the sampling and analysis of current levels at a time of very low values of contemporary weapon fallout will provide a more sensitive comparison with the baseline than does a comparison of the corresponding accumulations of the radionuclides in soil. In this case the comparison showed an excess of radionuclides at the coast compared with inland (associated with sodium from sea) as well as an excess over nuclear weapon fallout (Table 2). The extra ^{137}Cs could be attributed to sea-spray containing the concentration of seawater from the Irish Sea. For the actinides Pu and ^{241}Am, it is necessary to seek a mechanism of enrichment to explain the higher concentrations relative to sodium.

The radioactivity discharged by 1978 from Sellafield into the Irish Sea includes more than 12 kCi of Pu α activity and 600 kCi of ^{137}Cs (ref. 4). Most of the ^{137}Cs remains in solution whereas about 95% of the plutonium is removed to sediment[17]. The evidence summarized above points to a mechanism of physical transfer to land of a very small fraction of the radionuclides in the sea. Possible mechanisms are (1) suspension of the sea surface in the form of spray, either directly by wind or by bubble bursting, (2) injection of seawater and sediment into the air by waves breaking in the surf zone and (3) movement of sediment to intertidal regions and subsequent resuspension by wind. The second possibility, that involves the resuspension of sediment within the sea before release as enriched sea-spray, would satisfy the condition of enrichment that is required for the insoluble $^{239+240}$Pu (and perhaps ^{241}Am). In the case of the soluble ^{137}Cs there would be no enrichment. It has been shown that other means of enrichment are possible, for example, of the sea surface microlayer with stable trace elements[18,19]. More detailed work[20] has been started to elucidate the mechanism of sea-to-land transfer of these radionuclides in order to estimate the magnitude of the effect over the long term.

Effects of a cloned cell line with NK activity on bone marrow transplants, tumour development and metastasis *in vivo*

John F. Warner & Gunther Dennert

Department of Cancer Biology, The Salk Institute for Biological Studies, PO Box 85800, San Diego, California 92138, USA

Natural killer (NK) cells cloned in vitro *have been transferred into NK-deficient hosts. These cells have been shown to have a role in the rejection of allogeneic bone marrow grafts, resistance to both radiation-induced thymic leukaemia and challenge with melanoma tumour cells. It appears that NK cells have an important role in immune surveillance.*

THE low incidence of spontaneous tumours in congentially immunodeficient athymic 'nude' mice[1], which lack functional T cells has raised questions about the role of conventionally induced cytotoxic T lymphocytes (CTL) in the immunosurveillance of tumour formation. Attention has therefore been focused on 'so-called' nonspecific cellular mechanisms such as natural killer (NK) cells[2]. NK cells, which are present in 'nude' as well as normal mice, can lyse certain tumour cells *in vitro* spontaneously, and therefore may be an important primary line of defence against neoplastic formation *in vivo*[3]. The low frequency of NK cells in lymphoid organs and the lack of well-defined and unique NK cell surface markers have made

0028-0836/82/440031—04$01 00

the isolation and study of NK cells rather difficult but recently, murine NK cells have been established and cloned as permanent cell lines *in vitro*[4]. Such NK clones provide a powerful tool with which to explore the *in vivo* functions of these important and interesting cells.

Here we report the *in vivo* effects of an NK cell clone in three experimental animal models. The first involves the rejection of allogeneic bone marrow transplants, the second the inhibition of tumour metastasis, and the third the suppression of radiation-induced thymic leukaemia. First, we show that NK cell-deficient C57BL/6–beige mice[5,6], injected with cloned histocompatible NK cells, develop the ability, comparable to that of normal C57BL/6 mice, to reject allogeneic bone marrow grafts. The bone marrow rejection is specific for target structures primarily encoded by genes in the H–2D region of the murine major histocompatibility complex (MHC). Second, using the lung colony assay, we show that lung implantation of intravenously injected B16 melanoma tumour cells in cyclophosphamide-treated (that is, NK-deficient) C57BL/6 mice is markedly inhibited in those mice previously injected with syngeneic NK cells. Third, we demonstrate that the incidence of radiation-induced thymic leukaemia in C57BL/6 mice is dramatically reduced by intravenous administration of syngeneic cloned NK cells 3 months before the normal onset of thymic leukaemia. Taken together, these results support a role for NK cells in bone marrow graft rejection and in the surveillance of neoplasia.

Cloning of NK cells

As C57BL/6 mice were used to study the potential *in vivo* function of NK cells we have established and cloned NK cell lines from C57BL/6 mice for these experiments as previously described for BALB/c and BALB/c *nu/nu* cell clones[4,7]. C57BL/6 splenocytes were cultured in complete RPMI 1640 medium supplemented with concanavalin A (Con A) conditioned medium[4]. Cell cultures exhibiting NK activity were cloned by limiting dilution and individual isolates assayed for NK activity on a panel of NK-sensitive and resistant tumour targets[7]. The results showed that the cytolytic pattern of these clones was characteristic for NK cells and identical to that previously described for BALB/c NK clones. The cell-surface marker phenotype of the C57BL/6 NK clones was similar to that previously associated with cloned BALB/c NK cell lines[7], namely Thy 1.2$^+$, T200$^+$, Lyt 1$^-$, Lyt 2$^-$. The presence of dense granules imaged by electron microscopy was also characteristic of these C57BL/6 clones (manuscript in preparation). In the experiments described below, the C57BL/6 cell clone NK B61A2 was used.

Rejection of bone marrow grafts

Previous studies had shown that several positive correlations exist between NK activity *in vitro* and natural resistance *in vivo* to bone marrow transplants[8]. As C57BL/6–beige mice are genetically NK-deficient, they were used to study the potential role of cloned NK cells in the rejection of allogeneic marrow grafts. In a similar model, C57BL/6 mice were made NK-deficient by exposure to four, weekly 175-rad doses of γ-irradiation[9]. Both groups of NK-deficient mice were injected intravenously with 2×10^6 cloned NK B61A2 cells and 7 days later exposed to a lethal dose of γ-irradiation (850–950 rad) followed by transplantation with 2×10^6 allogeneic BALB/c bone marrow cells. Proliferation of donor-derived cells in the spleen (that is, CFU–S formation), indicative of repopulation of the lymphomyeloid system, was assessed 5–12 days after marrow transplantation by incorporation into splenocyte DNA of injected ^{125}I-labelled 5-iodo-2′-deoxyuridine (^{125}IUdR)[10,11]. Splenic repopulation by transplanted marrow cells was expressed as a percentage of retained radioactivity in the spleen. Results (Table 1*a*) show that normal C57BL/6 (H–2^b) mice reject BALB/c (H–2^d) bone marrow (that is, <0.05% ^{125}IUdR uptake), whereas beige mice and split-dose irradiated C57BL/6 mice are unable to reject allogeneic marrow transplants (that is, ^{125}IUdR uptake >0.5% which is equivalent to the syngeneic growth control of BALB/c marrow transplanted into irradiated BALB/c recipients).

In contrast, beige mice and split-dose irradiated C57BL/6 mice, previously injected with H–2 compatible cloned NK B61A2 cells, are capable of rejecting BALB/c bone marrow. Similar results were obtained in experiments assayed 12 days after marrow transplantation. A dose of 2×10^6 NK B61A2 cells was sufficient to cause complete marrow graft rejection in all injected animals when NK cells were administered between 2 and at least 30 days before marrow transplantation. However, when NK cells were administered shortly before marrow transplantation, the percentage of NK-injected mice able to reject marrow grafts was dependent on the dose of NK cells (data not shown).

Table 1 Rejection of allogeneic bone marrow by NK-deficient C57BL/6 mice injected with NK B61A2 cells

a, Normal C57BL/6, C57BL/6–beige (*bg/bg*), or C57BL/6 mice treated with four weekly doses of 175 rad γ-irradiation were used as bone marrow graft recipients. Shortly before bone marrow cell transfer, recipient mice were exposed to a lethal dose (850 rad) of ^{60}Co γ-irradiation. Donor marrow cells (2×10^6 cells per mouse) were injected intravenously into sex- and age-matched recipients. Proliferation of transplanted cells was assessed 5 days later by measuring the incorporation of ^{125}IUdR into splenocyte DNA[10,11]. Uptake of radioactivity was expressed as a percentage of retained radioactivity in the spleen. The geometric mean and standard error of the arithmetic mean for each group of mice (3–6 animals) are given. Irradiated recipients, syngeneic to the donors, were used as positive controls for uninhibited bone marrow growth (consistently $\geqslant$0.50% splenic ^{125}IUdR uptake). Irradiated mice not injected with marrow cells were used as negative controls for ^{125}IUdR incorporation (<0.05% splenic uptake). Groups of mice injected with NK cells received 2×10^6 cloned C57BL/6 NK B61A2 cells intravenously 7 days before bone marrow transplantation. The data presented are from experiments assayed on day 5; however, 12-day assays showed similar results. *b*, Marrow graft transplantation into C57BL/6–beige and C57BL/6-*bg*/+ recipients was done as in *a*, using bone marrow cells obtained from various H–2 recombinant mouse strains possessing *d* alleles at different regions within the H–2 gene complex. Some *bg/bg* mice were injected intravenously with 2×10^6 cloned NK B61A2 cells 7 days before lethal body irradiation and marrow transplantation (*bg/bg*+NK B61A2). Marrow growth control values, obtained by injecting donor cells into histocompatible recipients, were comparable to those values obtained by injecting cells from the same preparation into *bg/bg* recipients. C57BL/6 and C57BL/6 *bg*/+ recipients showed identical rejection patterns of bone marrow transplants.

Table 2 Effect on allogeneic marrow grafts of NK B61A2 cells and cell lines without NK activity

Recipient	Cell lines used for injection	NK activity of cell lines	Bone marrow donor	% Splenic ^{125}IUdR uptake
a (C57BL/6×C3H)F_1	—		C57BL/6	0.01±0.001

C57BL/6-*bg/bg*	CTLL-2	–	BALB/c	1.33±0.20

Bone marrow transplantation into irradiated normal and beige (C57BL/6×C3H)F_1 hybrid (*a*) or C57BL/6 (*b*) recipients was done as described in Table 1 legend using a 7-day assay. Some groups of mice were injected intravenously 7 days before marrow transplantation with 2×10^6 cells from various cell lines maintained in Con A conditioned medium which either express (+) or do not express (–) NK activity *in vitro* on YAC-1 target cells. Injected cell lines are the following: NK B61A2, a cloned cell line derived from C57BL/6; CTLL-2, a cell line derived from a C57BL/6 anti-BALB/c (H-2^b anti-H-2^d) mixed lymphocyte reaction[20]; BB1 and BC1, cell lines derived from C57BL/6–beige and (C57BL/6×C3H)F_1 mice, respectively, by culturing lymphoid cells in Con A conditioned medium. None of the cell lines, except NK B61A2, expresses NK activity. Growth control values for donor bone marrow were equivalent to those obtained in beige recipients and are not included.

As the phenomenon of marrow allograft rejection exhibits a unique specificity for antigens primarily encoded in the H-2D region[10–13] and to a lesser extent the H-2K region[14] of the MHC, it was important to determine the specificity of marrow graft rejection caused by cloned NK cells. NK cell-injected C57BL/6–beige mice were transplanted with bone marrow obtained from B10 and other congeneic mouse strains in order to map the genetic specificity of graft rejection. Results (Table 1*b*) show that NK-injected beige mice reject BALB/c (H-2^d) but not BALB.B (H-2^b) bone marrow which shows that H-2 encoded target determinants are responsible for rejection. Furthermore, when H-2 recombinant mouse strains are used as bone marrow donors, NK-injected beige mice reject transplanted marrow from donors possessing the H-2D^d allele [B10.A(18R)]. In contrast, relatively weak rejection of marrow cells expressing H-2K end disparity (B10.HTG and D2.GD) is observed[14], whereas H-2 identical bone marrow (B10) is not rejected. Several important conclusions can be drawn from these results: (1) a cloned NK cell line injected into syngeneic NK-deficient mice has an effect *in vivo*; (2) this function is specific in that H-2 disparate, but not H-2 identical bone marrow transplants are rejected; and (3) rejection is primarily, but not exclusively, directed towards antigenic determinants encoded by the H-2D region.

These findings raise the question of whether the effects observed are specifically due to the action of cells expressing NK activity. To demonstrate this, several kinds of controls were done. First, NK B61A2 cells were tested in NK-deficient semi-allogeneic (C57BL/6×C3H)F_1 beige hosts. Interestingly, in this model, NK B61A2 cells did not cause rejection of either C57BL/6 or C3H marrow transplants, although they do cause a significant but weak rejection of BALB/c allografts (Table 2*a*). Second, cell lines which do not express NK activity, but require Con A conditioned medium for their growth, do not cause bone marrow rejection. This is shown for several different cell lines. Cell line BC1, obtained from (C57BL/6×C3H)F_1 mice, grown in Con A conditioned medium and lacking NK activity, when injected into NK-deficient (C37BL/6×C3H)F_1 beige mice, does not cause rejection of C57BL/6, C3H or allogeneic BALB/c bone marrow (Table 2*a*). Similarly, cell line BB1, derived from C57BL/6-beige mice, which lacks NK activity, also fails to cause rejection of BALB/c bone marrow grafts when injected into C57BL/6–beige mice (Table 2*b*). Interestingly, the cell line CTLL-2, derived from a C57BL/6 anti-BALB/c (H-2^b anti H-2^d) mixed lymphocyte reaction[20], which also requires Con A conditioned medium for proliferation and expresses no NK activity, fails to cause bone marrow rejection (Table 2*b*). These results suggest that bone marrow rejection *in vivo* is caused by cell lines which express NK cytolytic activity *in vitro* and that cell lines merely grown in Con A conditioned medium are not sufficient to cause marrow allograft rejection.

An as yet unexplained observation is that the injection of NK B61A2 cells into (C57BL/6×C3H)F_1 mice leads to rejection of allogeneic BALB/c but not parental marrow grafts. Perhaps NK cells express exquisite *in vivo* H-2 specificity not obviously demonstrable *in vitro*, as NK B61A2 lyses tumour target cells and peritoneal exudate cells independent of the H-2 haplotype *in vitro* (unpublished results). Accessory cells and/or humoral factors may participate in the rejection of marrow grafts *in vivo*, as one or both components would be absent from NK cytotoxic assays *in vitro*. It is important in this respect that NK B61A2 exhibits antibody-dependent-cell-mediated lysis *in vitro* (unpublished results). Therefore, the

Table 3 Suppression of lung tumour colony formation in NK-deficient mice injected with NK B61A2

C57BL/6-CY	NK B61A2	+	1×10^5	43±18
C57BL/6-CY	CTLL-2	–	1×10^5	260±25
C57BL/6-CY	BC1	–	1×10^5	203±2

C57BL/6 mice injected intraperitoneally with cyclophosphamide (CY) (200 mg per kg) 4 days previously, were injected intravenously with various doses of B16/F10 melanoma cells[15]. Some mice were also given 2×10^6 cloned NK B61A2 cells, BC1 cells or CTLL-2 cells intravenously 3 h before tumour cell challenge. Pulmonary colonies were counted 3 weeks later after fixation in Bouin's solution and examination under a dissecting microscope. Mice were age- and sex-matched for each experiment. The mean and standard deviation of the number of tumour colonies per lung is presented.

* Mice given 4×10^5 tumour cells alone (*a*) died before the termination of the experiment so the number of tumour colonies in this group does not show a linear dose relationship. Experiments using C57BL/6–beige mice showed similar results

Table 4 Decreased incidence of radiation-induced thymic leukaemia in C57BL/6 mice injected with cloned C57BL/6 NK cells

Treatment		Cumulative thymoma incidence (mice with tumour/total no. of mice) Months post-irridadiation							
Irradiation	NK	3	4	5	6	7	8	9	% Incidence
–	–	0/12	0/12	0/12	0/12	0/12	0/12	0/12	0
+	–	0/12	3/12	5/12	8/12	10/12	10/12	10/12	83
+	+	0/12	0/12	0/12	1/12	1/12	1/12	1/12	8

Groups of 4-week old C57BL/6 mice were exposed to four weekly doses (175 rad) of ^{60}Co γ-irradiation[19]. One week after the final irradiation, mice were injected intravenously with $2–3\times10^6$ cloned NK B61A2 cells on a weekly basis for 4 weeks. Mice were observed up to 9 months later, and at death, necropsy was performed to determine the incidence of thymic leukaemia. Presented data are from a representative experiment and show the cumulative number of mice with thymic leukaemia relative to the total number of animals.

failure of NK B61A2 to reject parental marrow grafts as opposed to allogeneic grafts could be a reflection of naturally occurring antibody (that is, anti-allo antibody) in the (C57BL/6 × C3H)F_1 mice.

An important and related question is whether injection of NK B61A2 cells into NK-deficient mice directly reconstitutes the animal's NK activity or whether other cell types involved in the mechanism of transplant rejection are recruited. Migration studies have shown that only about 1% of the injected NK cells eventually end up in the spleen, a number which is probably too small to be detectable by conventional cytotoxicity assays but may be sufficient to cause bone marrow rejection. Even after 9 days, only low NK activity is detectable in splenocytes of NK-injected mice. This indicates that NK reconstitution is incomplete and would argue against rapid NK cell proliferation or massive recruitment of host NK cells as a result of NK B61A2 injection.

Effect of NK cells on melanoma

Further experiments explored the role of NK cells in the surveillance of neoplasia. Recent studies have implicated NK cells in the control of experimental metastasis of the C57BL/6 melanoma, B16/F10 (refs 15–17). In this model, either C57BL/6–beige or C57BL/6 mice made NK-deficient by prior injection of cyclophosphamide (day 4, 200 mg per kg)[18] are injected with melanoma cells. Tumour-challenged NK-deficient mice develop pulmonary tumour colonies 2–3 weeks later. Using this system, we examined the effect of adoptively transferred cloned NK cells on the development of B16 tumour colonies in the lungs of C57BL/6 mice. Cyclophosphamide-treated mice were injected with 2×10^6 NKB61A2 cells 3 h before intravenous tumour cell injection and the number of melanoma tumour colonies growing in the lungs was assayed 3 weeks later. Results show that mice injected with NK cells exhibit a 50–85% reduction in lung tumour colonies compared with controls (Table 3*a*). Moreover, tumour colonies were not detected in other organs of NK B61A2 injected mice, whereas control mice frequently showed additional tumours in the liver. In contrast, injection of either CTLL-2 or BC1 cells, which lack NK activity, into NK-deficient mice did not result in a decrease in lung tumour colonies (Table 3*b*). Experiments using C57BL/6–beige mice showed similar results (data not shown). Hence, injection of cells with NK activity into NK-deficient mice appears to cause inhibition of pulmonary tumour colonies. This demonstrates that cloned NK cells are able to perform a function *in vivo* already suggested by previous studies[15–17] in which spleen cell preparations high in NK activity were used.

Radiation-induced thymic leukaemia

The *in vivo* suppressive effects caused by this clone of cells with NK activity on B16 melanoma growth led us to investigate the potential antitumour activity of cloned NK cells on the development of radiation-induced thymic leukaemia. In this model, 70–90% of C57BL/6 mice, which are subjected to four weekly doses of 175–200 rad of γ-irradiation beginning at 4 weeks of age, develop lethal thymic leukaemia 3–5 months after the last irradiation[19]. Recent studies have shown that this leukaemogenic split-dose irradiation also results in severe depression of NK activity[9]. Therefore, C57BL/6 mice were exposed to leukaemogenic split-dose irradiation and divided into two groups, one of which was given four weekly injections of cloned NK B61A2 cells ($2–3\times10^6$ per mouse) after the last irradiation and the other left as control for leukaemia development. Results collected over 9 months show that ~80% of the irradiated control mice developed thymic leukaemia, whereas less than 10% of the irradiated mice injected with syngeneic NK B61A2 cells developed thymoma (Table 4).

We have noted the following observations in experiments currently under way. The lowest incidence of leukaemia occurs in mice injected with NK cells immediately after the last irradiation. Later injection of NK cells (that is 2–3 months after irradiation), at a time when NK activity may slowly reappear, does not seem to prevent development of leukaemia, as is also the case with early injection of cell lines not expressing NK activity. These findings suggest that split-dose irradiated NK-deficient mice, transfused at the proper time with cloned histocompatible NK cells, may become resistant to the development of radiation-induced thymic leukaemia.

Conclusions

Taken together, our observations suggest that NK cells have a crucial role in the mechanism of marrow graft rejection. This in turn may reflect their potential regulatory role in stem cell development and differentiation. Furthermore, NK cells may play an important role in the control of neoplasia. Our experiments, however, do not resolve the question of whether the effects exerted by these cloned NK cells are mediated directly or indirectly. They show, however, the significance of lymphocyte cloning techniques for examining the functional activity of lymphocytes and may point toward experimental approaches in the control of neoplasia.

---

A stretch of 200 kilobases (kb) of DNA from the I *region of the mouse major histocompatibility complex has been cloned and characterized. It contains the genes for the biochemically defined class II proteins* E_α, E_β *and* A_β. *DNA blot analyses suggest that the* I *region may contain only 6–8 class II genes. Correlation of our molecular map with the genetic map of the* I *region confines two of the five* I *subregions,* I–J *and* I–B, *to less than 3.4 kb of DNA at the 3′ end of the* E_β *gene where a hotspot for recombination has been observed. Indeed, the* I–A *and* I–E *subregions may be contiguous. If so, the* I–B *and* I–J *subregions are not encoded in the* I *region between the* I–A *and* I–E *subregions.*

THE major histocompatibility complex (MHC) in mice encompasses about 2 centimorgans of DNA on chromosome 17 and encodes three different classes of proteins involved in immune responses[1,2]. Class I and class II molecules are both integral cell-surface glycoproteins, whereas class III molecules are serum components of the complement system. Class I molecules, typified by the transplantation antigens, serve as restricting elements for the response of cytotoxic T cells to virally infected cells. Class II molecules, also called *I*-region-associated or Ia antigens, are encoded in the *I* region of the MHC. They regulate the recognition of foreign antigens on the surfaces of macrophages and B cells by T cells[3]. These interactions lead to high or low immune responses to antigenic determinants controlled by the so-called *Ir* (immune response) genes. The Ia antigens appear to be equivalent to *Ir* gene products[4]. Initially it was believed that the *Ir* genes might encode the presumably vast array of T-cell receptor molecules[5]. However, recent studies using serological and protein analyses have suggested a much more limited number of *Ir* or *Ia* genes. A genetic map of the MHC is shown in Fig. 1.

The *I* region has been divided by recombinational analysis into five subregions: *I-A*, *I-B*, *I-J*, *I-E* and *I-C*[6]. The *I-A* and *I-E* subregions contain at least four genes encoding the Ia antigens. The two biochemically well characterized Ia antigens, I-A and I-E, are heterodimers composed of a 33,000 to 35,000-molecular weight α chain and a 28,000 to 31,000-molecular weight β chain and are expressed primarily on B cells and macrophages. The A_α, A_β and E_β chains are encoded in the *I-A* subregion whereas the E_α peptide is encoded in the *I-E* subregion. The *I-J* subregion appears to encode one or more soluble T-cell factors and cell-surface antigens on T cells and macrophages which suppress immune responses. Although these I-J suppressor factors have been serologically defined, their biochemical characterization is only beginning[7–9]. The *I-B* and *I-C* subregions are more controversial[4,6]. They were originally defined based on their apparent control of certain types of immune responses.

An important characteristic of the MHC is the extreme polymorphism of class I and class II molecules[10]. For example, there appear to be over 100 alleles each for the K and D genes of the class I category. Whereas the A_β and E_β loci also are very polymorphic, the A_α and E_α loci exhibit a limited degree of polymorphism. The constellation of alleles present in a particular MHC is called a haplotype. For example, the inbred mouse strain that we have studied, BALB/c, has a *d* haplotype MHC and expresses class I and class II chains denoted K^d, D^d, A^d_α, A^d_β, E^d_α, E^d_β, and so on.

Our initial studies on the genes of the major histocompatibility complex focused on the class I genes[11–13]. From a cosmid genomic library constructed from BALB/c sperm DNA, we isolated 54 class I clones which could be ordered into 13 clusters spanning 837 kb of DNA and contained 36 distinct class I genes[14]. This study demonstrated the effectiveness of cosmid vectors which incorporate very large eukaryotic DNA inserts (~40 kb) in the definition and linkage of MHC genes. Subsequently, we used the techniques of gene transfer to correlate many of these genes with their serologically defined gene products and have initiated studies into the analysis of their functions in cell–cell communication[15–17].

To extend this analysis to class II genes in the *I* region, we have used cDNA clones coding for human class II α and β chains[18,19] and using chromosomal walking procedures, have isolated about 200 kb of contiguous DNA from the *I* region of the inbred BALB/c mouse. Genes for three of the four biochemically defined class II chains, E_α, E_β and A_β, have been identified as has a fourth class II gene, denoted $E_{\beta 2}$, that has not been described previously. Correlation of our molecular map with the genetic map of the *I* region places these genes in the *I-A* and *I-E* subregions and confines the *I-B* and *I-J* subregions to less than 3.4 kb of DNA at the 3′ end of the E_β gene.

cDNA clones for human class II α and β chains

In man, the best known class II antigen is HLA-DR, which exhibits homology for *I-E* gene products of the mouse[20,21]. Other loci exist in man for different class II antigens, such as DC[22] (probably identical with DS[23]) and SB[24]. It appears that the human HLA-DC antigens are the equivalent of the mouse I-A antigens[23,25]. Several laboratories have reported the cloning and sequence analysis of cDNA complementary to human messenger RNAs encoding class II α and β chains[18,19,26–30]. Full-length cDNA clones for the α chain of HLA-DR were isolated from a cDNA library made from the human Raji cell line[18]. One of these clones, referred to as DR_α, is used here as a probe for the identification of the corresponding mouse genes.

Full-length cDNA clones for the polymorphic β chain of HLA-DR, as well as clones for another 'Ia-like' β chain, clearly distinct from HLA-DR, have been isolated from heterozygous and homozygous human cell lines[19]. The genes for these two different class II β chains show a high degree of polymorphism when analysed directly by Southern blot hybridization (C.W. *et al.*, in preparation). Our cDNA clones for this 'Ia-like' β chain are very similar to the β-chain clones reported by

0028–0836/82/440035—08$01 00

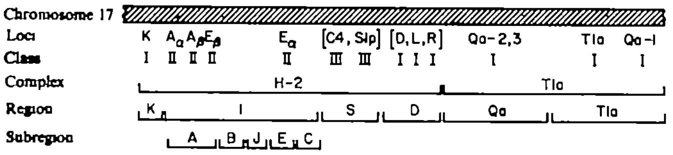

Fig. 1 Genetic map of the major histocompatibility complex of the mouse. The *K*, *D*, *L* and *R* genes encode the transplantation antigens which are found on all somatic cells, whereas the *Qa-2,3*, *Tla* and *Qa-1* genes encode class I molecules which are restricted in their expression to haematopoietic cells. The class III genes *C4* and *Slp* encode C4 components in the *S* region. Genes in brackets have not been mapped with respect to each other. Recombination frequencies are in centimorgans and taken from ref. 2. The centromere is located to the left.

others[27,29], and they are all clearly different from HLA-DR_β-chain genes[19,31]. As will be shown here, hybridization of this human 'Ia-like' β-chain gene to mouse DNA shows strongest homology with the A_β gene. Because the mouse A_α and human HLA-DC_α chains appear homologous[23,25], we feel that the 'Ia-like,' non-DR β chain is probably a component of the HLA-DC molecule. In this study, we therefore refer to this β-chain cDNA clone as DC_β.

Cloning of 200 kb of DNA from the *I* region

We isolated the mouse E_α gene by screening a cosmid genomic library previously constructed from BALB/c sperm DNA with the human DR_α-chain cDNA clone. This screen yielded the four overlapping cosmid clones 39.1, 17.2, 32.1 and 17.3 which defined a region of about 60 kb of DNA with the E_α gene in the middle (Fig. 2). We then isolated single-copy probes 4 and 8 from the 5′ and 3′ ends, respectively, of this 60-kb region and re-screened our cosmid library. Two overlapping clones (24.2 and 8.4) were obtained with probe 4 and eight overlapping clones (57.2, 52.4, 60.3, 21.1, 54.2, 16.2, 47.3 and 55.2) with probe 8. This chromosomal walking procedure was repeated once more with probes 2 and 9 which yielded the cosmid clones 41.1, 29.1 and 7.1 (Fig. 2). Finally, cosmid clone 34.2 was isolated by screening the library with the human DC_β-chain cDNA clone.

These 18 overlapping cosmid clones represent about 200 kb of DNA from the *I* region (Fig. 2). Although cosmid clones may delete certain DNA segments[14], there is no evidence for observable deletions since most of the DNA in this 200-kb region is represented by two or more independently generated cosmid clones. Independent evidence for the integrity of the chromosomal map was obtained by Southern blot analyses of BALB/c liver DNA cleaved with four different restriction

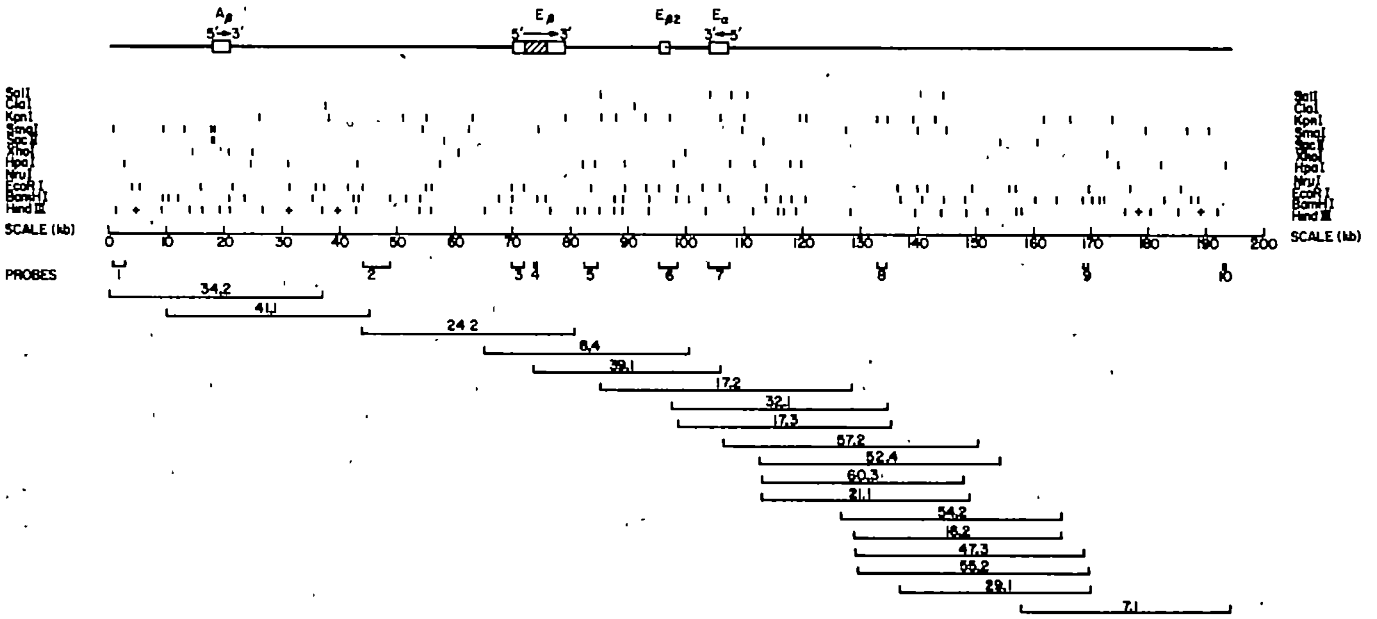

Fig. 2 Molecular map of 200 kb of the *I* region from the BALB/c mouse defined by 18 overlapping cosmid clones and containing four class II genes. Our cosmid BALB/c sperm DNA library, distributed on 66 nitrocellulose filters, contains about 250,000 colonies (representing three genome equivalents)[14]. It was hybridized sequentially with the DR_α-chain cDNA clone 39-1 prepared from human Raji cell line mRNA[18], probes 4 and 8 from cosmids 39.1 and 32.1, probes 2 and 9 from cosmids 24.2 and 55.2, and the DC_β-chain cDNA clone[19] isolated from Raji cell mRNA. For hybridization the *Pst*I fragments comprising the inserts of DR_α and DC_β (DR_α 39-1: 450 and 650 bp; DC_β: 350 and 800 bp in length; corresponding to the 5′ and 3′ part of the cDNAs, respectively) and the appropriate fragments from the cosmid clones (see below) were isolated by agarose gel electrophoresis and electroelution onto DE81 paper[44] and labelled by nick-translation to a specific activity of about $1-3\times10^8$ c.p.m. μg^{-1}. Hybridization was carried out for 16–18 h at 65 °C with a total of 10^5-10^6 c.p.m. ml^{-1} in 5×SSC, 10% dextran sulphate, 5× Denhardt's solution, 5 mM EDTA, 0.1% SDS, 150 $\mu g\ ml^{-1}$ denatured salmon sperm DNA and 1–2 $\mu g\ ml^{-1}$ *Hae*III-digested, denatured pBR322 DNA and 50 $\mu g\ ml^{-1}$ denatured BALB/c DNA to compete for contaminating restriction fragments containing pBR322 or repetitive mouse DNA sequences in the nick-translated probes. The filters were then washed at 65 °C twice for 30–60 min each in 3× SSC, 0.1% SDS and subsequently treated the same way in 2× SSC, 0.1% SDS when the screen was with the human cDNA clones, or in 1× SSC, 0.1% SDS when probes from the cosmid clones were used. Filters were exposed for 1–2 days with intensifying screens, positive colonies were picked from a replica set of the library kept frozen at −80 °C and purified by a second round of plating and hybridization as described previously[14] and above. For the isolation of the 18 overlapping cosmid clones, the same set of filters was used without any treatment between the individual hybridizations. To avoid picking of previously isolated cosmid clones, autoradiograms were compared with those from the last round of hybridization to identify only new cosmid clones. Plasmid DNA was then isolated from the cosmid clones as previously described and mapped with the restriction enzymes indicated by single and double digestions. A + between two restriction sites indicates the presence of more sites in this region for the same enzyme. The location and orientation of the class II genes shown as open boxes was determined by Southern blot analyses of restriction fragments from the cosmid clones with the separated 5′ and 3′ *Pst*I fragments from the human cDNA clones as hybridization probes. The sizes of the open boxes, therefore, give maximal lengths for the coding regions cross-hybridizing to our human probes. The hatched area in the E_β gene indicates the location of an intervening sequence presumably between the exons for the $\beta1$ and $\beta2$ domains[29,37] since the 5′ and 3′ probes from DC_β hybridize exclusively to the left and to the right of the intervening sequence, respectively (the internal *Pst*I site used to generate these probes is located around amino acid residue 90 at the border between the $\beta1$ and $\beta2$ domains). The 10 probes isolated from the 200-kb region were identified as being free of repetitive DNA sequences by their lack of hybridization to total mouse DNA as a labelled probe[45]. They were then shown to be composed of single-copy sequences by Southern blot hybridization against mouse genomic DNA. The 10 probes were isolated by agarose gel electrophoresis[44]. They represent the following restriction fragments: (1) 2-kb *Sma*I–*Hpa*I fragment from clone 34.2; (2) 4.7-kb *Eco*RI–*Bam*HI fragment from clone 24.2; (3) 2-kb *Eco*RI fragment from clone 24.2, subcloned into M13mp8; (4) 500-bp *Sau*3A fragment from clone 39.1 isolated from a 2.7-kb *Bam*HI fragment which extended into vector sequence; (5) 2.3-kb *Hin*dIII fragment from clone 39.1; (6) 3.2-kb *Eco*RI fragment from clone 8.4; (7) 3.4-kb *Sal*I fragment from clone 32.1, subcloned into M13mp8; (8) 1.6-kb *Kpn*I fragment from clone 32.1; (9) 800-bp *Sau*3A fragment from clone 55.2 isolated from a 2.9-kb *Bam*HI–*Nru*I fragment which extended into vector sequence; (10) 500-bp *Sau*3A fragment from clone 7.1 isolated from a 2-kb *Hpa*I–*Nru*I fragment which extended into vector sequence.

enzymes (*Eco*RI, *Bam*HI, *Kpn*I and *Hin*dIII) and hybridized with 10 single-copy probes scattered throughout the 200-kb region (Fig. 2 and below). In all cases the sizes of the genomic fragments agreed with those predicted by the map in Fig. 2. For example, Fig. 3 shows that probe 2 identified unique *Eco*RI, *Bam*HI, *Kpn*I and *Hin*dIII fragments in BALB/c DNA of 11, 6, 13 and 11.5 kb, respectively, which are in agreement with the restriction map established by the overlapping cosmid clones 41.1 and 24.2 (Fig. 2). These results confirm the small overlap between the two cosmid clones based on hybridization data and argues against major deletions or rearrangements even in this region, mainly defined by single cosmid clones.

The cloned *I* region contains four class II genes

It was expected that the human DR$_\alpha$-chain cDNA clone would hybridize to the mouse E$_\alpha$ gene because of N-terminal amino acid sequence homologies (refs 20, 21 and E. Sung *et al.*, in preparation) and known serological cross-reactions[32]. The gene identified in the middle of the 200-kb region with the human DR$_\alpha$ cDNA clone was subcloned and sequenced. The N-terminal amino acid sequence it encodes is 98% homologous to the E$_\alpha$ chain of the *k* haplotype (E. Sung *et al.*, in preparation) and the entire coding region is ~80% homologous to the human DR$_\alpha$ sequence at the DNA level[33]. We therefore believe that this class II gene is the mouse E_α^d gene and demonstrate below that the E$_\alpha$ gene maps into the *I-E* subregion.

As shown in Fig. 2, the E$_\beta$ gene was identified about 30 kb proximal to the E$_\alpha$ gene (the order of class II genes appears to be: centromere-A$_\alpha$-A$_\beta$-E$_\beta$-E$_\alpha$[34,35]). This class II gene was detected by hybridization to a chemically synthesized, 32-fold degenerate oligonucleotide probe 15 nucleotides in length specific for the E_β^k polypeptide. As shown in Fig. 4, this probe hybridized to a 4.8-kb *Bam*HI fragment spanning the 5′ half of the E$_\beta$ gene (see Fig. 2) in cosmids 24.2 and 8.4. This oligonucleotide probe did not hybridize to any other DNA fragment from the 200 kb of cloned *I* region. The E$_\beta$ gene also cross-hybridizes to the 5′ and 3′ probes (see below) of the human DC$_\beta$ cDNA clone. As we shall demonstrate later, this class II gene maps to the *I-A* subregion and is the site of crossing-over in the recombinant congeneic strain B10.GD as predicted from serological and biochemical analyses[34,36]. Accordingly, we believe we have correctly identified the mouse E$_\beta$ gene.

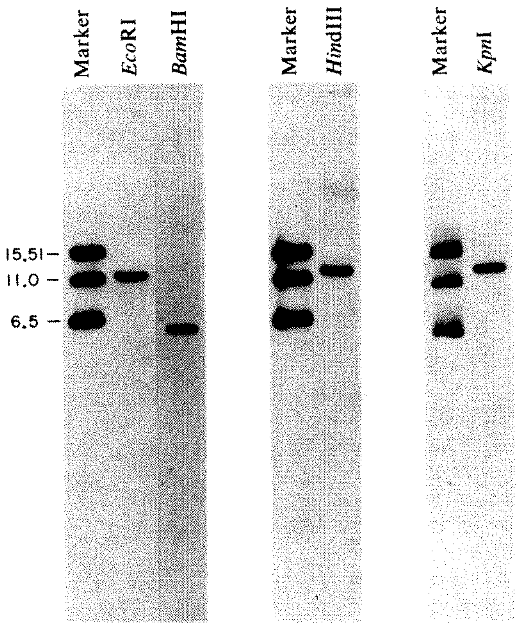

Fig. 3 Southern blot analysis of BALB/c DNA with single-copy probe 2. Ten μg of BALB/c liver DNA each was digested to completion with the enzymes indicated, separated on a 0.55% agarose gel and transferred to nitrocellulose filters. Hybridization with probe 2 (Fig. 2) was as described in Fig. 2 legend except that cold pBR322 DNA was omitted, probe concentration was 10^6 c.p.m. ml^{-1}, and the washes after hybridization were twice in 3×SSC, 0.1% SDS, and twice in 0.1×SSC, 0.1% SDS for 15 min each at room temperature. Sizes of DNA marker fragments are indicated in kilobase pairs.

A second class II *β* gene was identified between the E$_\beta$ and E$_\alpha$ genes by cross-hybridization to the human DC$_\beta$ cDNA clone. This gene hybridizes to the 3′ but not to the 5′ portion of the human DC$_\beta$ clone. The 5′ and 3′ probes from DC$_\beta$ were generated by *Pst*I digestion which cuts around amino acid

Vertical bars indicate presumed locations of crossing-over. Dots are given where the origin of the region is unknown. Parentheses for *H-2* alleles mean that their origin has only been deduced from the composition of the parental haplotypes. Parentheses for the parental haplotypes of strain A indicate that the *a* haplotype has not been derived from a known cross. Strains B10.RSF-1, TBR-2, B10.RSB-1, B10.RSB-2, B10.RSB-3, B10.RSB-4, B10.RSB-5, B10.F(14R), B10.RPD-1 and B10.RPD-2 were from C. David, B10.GD and B10.TL from J. Klein and C3H from the Jackson Laboratories. All other strains were raised in our colony (J.F.).

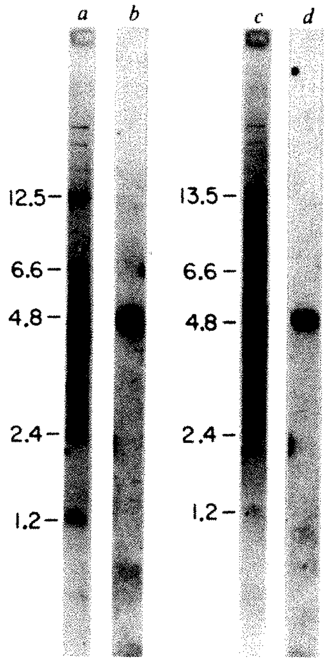

Fig. 4 Identification of the E_β gene in cosmids 8.4 and 24.2 by hybridization to a specific oligonucleotide probe. Cosmid clones 8.4 and 24.2 (0.25 μg each) were digested with *Bam*HI, separated on a 0.55% agarose gel and transferred to nitrocellulose filters. The hybridization probe, composed of a mixture of 32 15-mer oligonucleotides, was synthesized on polymer support using the phosphoramidite nucleoside chemistry[46]. The heterogeneous nucleotide sequence of the probe was based on the sequence Glu-Cys-His-Phe-Tyr (E. Sung *et al.*, in preparation) for residues 15 to 19 of the E^k_β chain. The probe was labelled with T4 polynucleotide kinase and [γ-^{32}P]ATP[47]. Hybridization was at 37 °C in the buffer described in Fig. 2 legend (except that the pBR322 and mouse DNAs were omitted) for 24 h with 5×10^5 c.p.m. ml^{-1}. The filters were washed twice for 15 min at room temperature in 3×SSC, 0.1% SDS and exposed with intensifying screens overnight. Sizes of DNA fragments are in kilobase pairs. *a* And *c* represent lanes containing ethidium bromide-stained DNA fragments from cosmids 8.4 and 24.2, respectively. *b* And *d* represent lanes containing autoradiograms of *a* and *c*, respectively, after hybridization.

residue 90 thereby separating the coding sequence for the first and second external domains[19,37]. A genomic fragment encoding the 5′ end of the E_β gene (probe 3, Fig. 2) also shows no hybridization to this second β gene. Moreover, this gene (probe 6, Fig. 2) hybridizes to the 3′ exons of the E_β gene but not detectably to the A_β gene on genomic blots in stringent conditions. Accordingly, this class II gene is E_β-like and we have denoted it $E_{\beta2}$. The 5′ exons of gene $E_{\beta2}$ might either be missing or so diversified that they no longer cross-hybridize to the corresponding mouse E_β and human DC_β probes. Thus, $E_{\beta2}$ might either be a pseudogene or another functional β gene whose product has not yet been identified by serological methods.

About 50 kb proximal to the E_β gene, a third class II β gene was identified with the human DC_β cDNA clone. As we shall see subsequently, this gene maps to the *I-A* subregion and represents the strongest band in a Southern blot analysis of BALB/c DNA with the human DC_β probe. Because this gene is distinct from the other two more closely related E_β-like genes by Southern blot analysis, it seems to be the A_β gene. Direct DNA sequence analysis has confirmed that the N-terminal amino acid sequence it encodes is identical in all positions that can be compared with the A^d_β protein sequence (M. Malissen, unpublished results).

The class II genes identified in the 200-kb region have several interesting features. First, the orientation of these genes has been determined with probes specific for the 5′ and 3′ ends of the class II genes isolated from the human DR_α and DC_β cDNAs. The E_α gene has a 5′ to 3′ orientation that is opposite of that for the A_β and E_β genes (Fig. 2). Second, there is a large intervening sequence in the E_β gene that presumably separates the exons encoding the two external domains of the β chain (see Fig. 2 legend). Third, the identification of probably three of the four genes encoding serologically defined class II polypeptides, suggests that we have already cloned a major fraction of the *I* region. Direct confirmation that these genes do indeed encode the class II polypeptides will come from gene transfer and expression studies.

The BALB/c genome seems to contain two α and four to six β genes

To estimate the number of class II α and β genes in the mouse genome, we carried out Southern blot analyses in low stringency conditions using as probes the mouse E_α gene and the human DC_β cDNA clone. These data suggest that there is a very limited number of class II genes. Figure 5*a* shows that the α probe detects the two *Eco*RI fragments of the E_α gene and a third fragment which could represent the A_α gene. Thus there appear to be only two class II α genes in the mouse genome. The human β chain cDNA probe (Fig. 5*b*) detects the two *Bam*HI fragments comprising the E_β gene and the *Bam*HI fragments containing the A_β and $E_{\beta2}$ genes. In addition to these cloned β genes, there are two or three extra bands presumably representing one to three additional β genes in the mouse genome. The human cDNA probe hybridizes most strongly to the A_β gene, suggesting that the DC_β cDNA clone represents the human homologue to the mouse A_β gene. Similar numbers of restriction fragments and presumably β genes are present in human DNA (Fig. 5*b* and C.W. *et al.*, in preparation). These data suggest that there are four to six β genes in the mouse genome. It should be stressed that there may be additional class II genes not sufficiently homologous to be detected by the α and β probes in our hybridization conditions. We can screen for these class II genes as well as for other genes located in the *I* region using the cosmid clones to examine the messenger

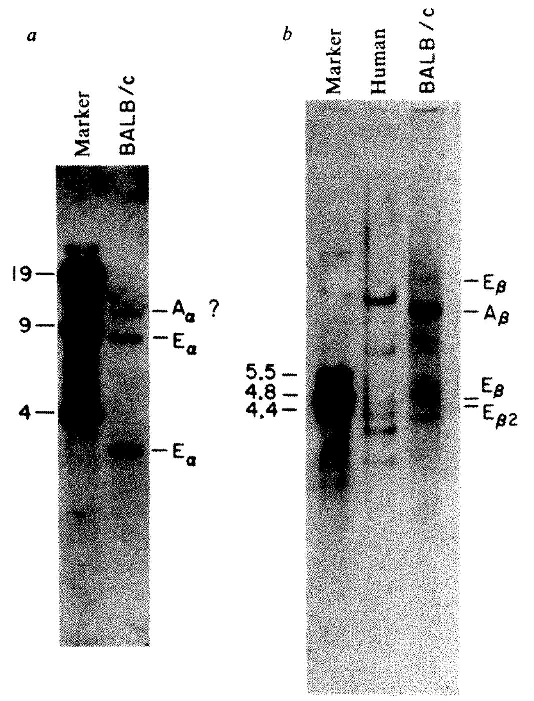

Fig. 5 Southern blot analyses of human and mouse DNAs with the mouse E_α gene and the human DC_β cDNA clone. 5–10 μg of BALB/c liver and human DNAs were digested to completion with restriction enzyme, separated on a 0.55% agarose gel, transferred to nitrocellulose filter and hybridized using the conditions described in Fig. 3 legend except that mouse DNA was omitted and the final wash was at 65 °C in 2×SSC, 0.1% SDS. Sizes of marker DNA fragments are given in kilobases. Cloned DNA fragments containing identified class II genes are indicated. *a*, BALB/c DNA was digested with *Eco*RI and hybridized with probe 7 (see Fig. 2). *b*, Human and mouse DNAs were digested with *Bam*HI and hybridized with the insert of the DC_β cDNA clone.

Fig. 6 Summary of mapping data obtained by Southern blot analyses of recombinant congeneic strains and strains containing the parental haplotypes with eight different single-copy probes from the 200-kb region. The top of the figure gives the organization of the cloned 200-kb region and indicates the location of the probes used for Southern blot hybridizations. The horizontal bars marked by different symbols show the origins of the *I-A* and *I-E* subregions schematically. Vertical lines separate the *I-A* and *I-E* subregions in the recombinants. Restriction fragments detected by the probes are denoted by the enzyme used and their sizes in kilobase pairs. For probe 6 only the fragments comprising the $E_{\beta2}$ gene are listed; the fragments comprising the E_β gene detected with probe 6 due to cross-hybridization are not given. For probe 7 the weakly cross-hybridizing fragments perhaps containing the A_α gene are not listed. It should be emphasized that mouse strains of independent origin containing identical *H-2* alleles in the *I* region (BALB/c and B10.D2; C3H and A) showed no difference when analysed with our probes.

RNAs produced by B cells, T cells and macrophages. Indeed, an additional class II gene exhibiting low homology to the E_α gene has been identified between the A_β and E_β genes with B cell-specific cDNA as a probe (M. Davis, unpublished results).

The E_α and E_β genes are present in strains not expressing I–E molecules

Four inbred strains of mice of independent origin (*b*, *f*, *q*, *s* haplotypes) do not express the I-E molecule on the cell surface[38]. Two of these haplotypes (*b* and *s*) express the E_β polypeptide in the cytoplasm but fail to express the E_α polypeptide. Two others (*f* and *q* haplotypes) express neither the E_β nor the E_α polypeptides. We have used our E_α and E_β probes in Southern blot analyses to examine the DNAs of these so-called nonexpressor strains for the presence of these genes. Clearly the E_α and E_β genes are present in all nonexpressor strains (Fig. 6). Accordingly, the failure to express these class II genes is not a consequence of the deletion of the entire gene. Several different mechanisms might be responsible for the loss of expression at the transcriptional or translational levels.

Correlation of our molecular map with the genetic map of the *I* region

Immunogeneticists have divided the *I* region into five subregions by recombinational analysis of various immune responsiveness traits[6]. The various recombinant congeneic strains that we have analysed join in the *I* region two out of four independently derived haplotypes (*d*, *b*, *k* and *s*) which are represented by the inbred mouse strains BALB/c, C57BL/6, A, and A.SW, respectively. The inbred strain A (*a* haplotype) is a natural recombinant between *k* and *d* haplotype genes; since the region of interest to us in this paper in strain A is of *k* haplotype origin we will use *k* instead of *a* when we refer to the haplotype of this strain (see Table 1).

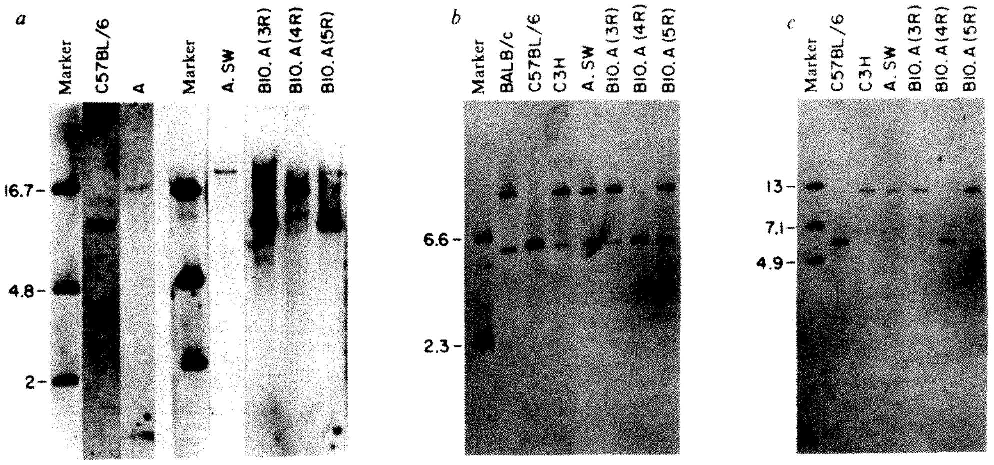

Fig. 7 Southern blot analyses of three recombinant congeneic mouse strains and of strains containing their parental haplotypes with probes 3, 4 and 5; 5–10 μg of mouse liver DNAs were digested to completion with restriction enzymes and after gel electrophoresis and transfer hybridized with single-copy probes in the conditions described for Fig. 3 except that the final washes were twice at 65 °C in 0.1 × SSC, 0.1% SDS for 15 min each. Sizes of DNA marker fragments are in kilobase pairs. *a*, Digests were done with *Kpn*I and the filters were hybridized with probe 3. *b*, *Eco*RI and probe 5. *c*, *Eco*RI and probe 4.

We correlated our molecular map with the genetic map of the *I* region through the analysis of restriction enzyme site polymorphisms as follows. First, 10 single-copy probes from various regions of the 200 kb of cloned DNA were isolated (Fig. 2). By Southern blot analyses of mouse DNA, these probes generally hybridized to single restriction enzyme fragments. Second, these single-copy probes were used to define restriction enzyme site polymorphisms between the four different haplotypes. Third, the polymorphic restriction fragments representing alternative forms of a genetic trait were used to map the probe into an appropriate *I* subregion through the analysis of a panel of recombinant strains. For example, probe 3 representing the 5′ half of the E_β gene detected 24.6-, 16.7- and 9.6-kb *Kpn*I fragments in the DNAs of A.SW (*s* haplotype), A (*k* haplotype), and C57BL/6 (*b* haplotype) mice, respectively (Fig. 7*a*). When the three intra-*I* region recombinants B10.A(3R), B10.A(4R) and B10.A(5R) were analysed with probe 3, a 9.6-kb *Kpn*I fragment was detected in 3R mice, a 16.7-kb *Kpn*I fragment was detected in 4R mice, and a 9.6-kb *Kpn*I fragment was detected in 5R mice (Fig. 7*a*). These data indicate that probe 3 is derived from a region which is of *b*-haplotype origin in 3R and 5R mice but of *k*-haplotype origin in 4R mice. Only the *I–A* subregion or the *K* region could correlate with these restriction site polymorphisms in the three recombinants (Table 1). Since probes 1 and 2 which are located proximal to probe 3 also map to the *I–A* subregion (Fig. 6), we conclude that probe 3, which encodes the 5′ half of the E_β gene, maps to the *I–A* subregion. These observations agree with the genetic map.

The surprising finding was that probe 5, which is located ~13 kb distal to probe 3, already maps into the I–E subregion although the genetic map places two additional subregions, *I–B* and *I–J*, between *I–A* and *I–E*. Figure 7*b* shows that probe 5 detects a 12.2-kb (and a 6.0-kb) *Eco*RI fragment in haplotypes *d*, *k* and *s* but a 6.2-kb (and a 6.0-kb) *Eco*RI fragment in the *b* haplotype. This polymorphism between the *b* and the *k* haplotype allows us to map probe 5 by analysis of the recombinants 3R, 4R and 5R unambiguously into the *I–E* subregion (Fig. 7*b*, Table 1). We further analyse this point below.

The finding that the two most proximal probes 1 and 2 still map into the *I–A* subregion is evident from an analysis of DNAs from B10.TL and A.TL mice and also places the A_β gene in the *I–A* subregion (Fig. 6). The $E_{\beta 2}$ gene (probe 6) and the E_α gene (probe 7) map in the *I–E* subregion (Fig. 6). With probes 8 and 9, isolated from the region distal to the E_α gene, it was more difficult to detect restriction enzyme site polymorphisms. With probe 8 we failed to detect polymorphic restriction fragments. Probe 9, which is located about 60 kb distal to the E_α gene, still maps into the *I–E* subregion (Fig. 6). In at least two recombinant congeneic strains, B10.RPD-1 and B10.RPD-2, probe 10, 25 kb distal to probe 9, maps outside the *I–E* subregion, presumably in the *I–C* subregion or the *S* region (not shown). However, in strain B10.F(14R), probe 10 still maps to the *I–E* subregion, indicating that the recombination event in 14R mice has occurred distal to the recombinational events in RPD-1 and RPD-2 mice. These results suggest that the *I–E* subregion is between 90 and 120 kb long.

The *I–B* and *I–J* subregions are confined to a 3.4-kb region of DNA

To determine more precisely the size of the chromosomal region containing the *I–B* and *I–J* subregions, we analysed nine inbred congeneic strains with recombination events between the *I–A* and *I–E* subregions. Through Southern blot analyses, we established the restriction maps for the parental haplotypes (*d*, *b*, *k* and *s*) for a region of 27 kb of DNA around the E_β gene using probes 3, 4 and 5 (Fig. 8). Polymorphic restriction enzyme sites which determine by their presence or absence in the appropriate recombinants the rightward and leftward boundaries for the recombination events are circled. The regions between these boundaries which are of undetermined origin in the recombinants, according to our present analysis, are shaded in Fig. 8.

The Southern blotting data for probes 3, 4 and 5 which led to these conclusions are summarized in Fig. 6. Several interesting points can be made from these analyses. All polymorphic restriction enzyme sites which we have analysed around the E_β gene map either to the *I–A* or *I–E* subregions (Fig. 8). No site has been mapped to the *I–B* or *I–J* subregion as defined by the appropriate recombinant strains. According to our present analysis, the maximal distance between the recombination point in B10.GD mice separating the *I–A* from the *I–B* subregion and the recombination point in B10.A(3R) separating the *I–J* from the *I–E* subregion is 3.4 kb. Figure 8 shows that the genome organization around the junction of the *I–A* and *I–E* subregions is very similar in the four mouse strains analysed which are of independent origin. Thus, one cannot postulate that a major deletion or rearrangement affecting the *I–B* and *I–J* subregions has occurred in the BALB/c mouse as compared with parental strains of the *b*, *k* or *s* haplotypes used to generate the recombinants defining the *I–B* and *I–J* subregions.

The *I–J* product may be encoded outside the *I* region

The results described above map the boundaries of the *I–A* and *I–E* subregions into a segment of DNA that is 3.4 kb. This region includes the 3′ half of the E_β gene. Indeed, if the E_β genes of the recombinant congeneic strains B10.A(3R) and B10.A(5R) are identical, as is suggested by peptide map analysis[39], the gap between the *I–A* and the *I–E* subregions may be less than 1 kb. We draw this conclusion because hybridization analysis with the human class II β probe indicates that the E_β gene extends beyond the *Hin*dIII restriction enzyme site in this region of the BALB/c genome (Fig. 8). The rightward boundary for the recombination event in B10.A(3R) and B10.A(5R) mice is marked by the polymorphic *Eco*RI restriction site 1 kb distal to this *Hin*dIII site (see Fig. 8).

This does not leave much DNA to encode the traits of the *I-B* and *I-J* regions. Indeed, the *I-B* subregion has only been defined based on the control of certain immune responses[6]. Recently, a controversy has arisen as to whether the *I-B* subregion exists in that the immune responses it controls may actually be regulated by both the I-A and I-E class II molecules[40]. Cloning studies and DNA sequence analyses of the recombinant regions defining the *I-B* subregion should allow us to localize this subregion even more precisely and, indeed, to determine whether it exists.

The *I-J* subregion apparently controls the expression of two or more serologically defined I-J gene products[41–43]. Several models may explain the gene or genes encoding I-J product(s). First, the I-J gene may be encoded outside the *I* region. This possibility cannot be excluded because the generation of the recombinant congeneic strains used to define the *I-J* subregion also involved recombination events outside the *I* region on chromosome 17. However, this possibility seems unlikely because I-J appears to segregate with the *I* region and not with any other region of the *H-2* complex. Second, expression of the I-J gene product may be controlled by a regulatory element which is encoded in this 3.4-kb region. Again this possibility seems unlikely because of the polymorphism observed in congeneic mice with identical background genes (that is, non-*I*-region genes). Third, I-J polypeptides might have been selected during ontogeny from a pool of variants for their ability to bind the E_β polypeptide in interactions between suppressor T cells and B cells or macrophages. Mouse strains polymorphic for E_β as well as recombinants affecting the E_β gene would thus select for different I-J polypeptides. The I-J polypeptide therefore seems to be under control of a locus overlapping the E_β gene, although its structural gene(s) would map elsewhere. Fourth, the I-J product may arise from RNA splicing patterns involving a polymorphic exon encoded between the *I-A* and *I-E* subregions and additional, nonpolymorphic exons encoded in the *I-A* or *I-E* subregions. This model could be analogous to the alternative RNA splicing patterns seen for the secreted and membrane forms of immunoglobulin heavy chain genes. Finally, the I-J and E_β polypeptides may be identical. The I-J chain, however, may differ in its antigenic properties from the E_β chain because of post-translational modifications such as glycosylation, or because of conformational differences if it is associated with a polypeptide different from E_α or alternatively, if it occurs as a single polypeptide chain on the surface of T suppressor cells.

Studies in progress should allow us to distinguish the first three from the latter possibilities by using a subcloned DNA segment between the *I-A* and *I-E* subregions to carry out RNA blot analyses on messenger RNAs from T-cell hybridomas expressing I-J gene products. The last two hypotheses would suggest that this region should cross-hybridize to I-J messenger RNAs, whereas the former three possibilities argue that the structural gene for the I-J polypeptide lies outside the *I* region and, accordingly, no cross-hybridization should be observed. We will also determine by cloning and sequencing, the exact location of the recombination points in, for example, B10.A(3R) and B10.A(5R) mice which define the leftward and rightward borders of the *I-J* subregion. Indeed, it is possible that the *I-A* and *I-E* subregions will be contiguous with no intervening DNA that could encode the *I-B* or *I-J* subregions. If so, the *I-B* and *I-J* subregions cannot be located between the *I-A* and *I-E* subregions.

Recombination in the *I* region is sharply localized in and around the E_β gene

The recombination events which occurred in nine independently generated recombinant congeneic mice between the *I-A* and *I-E* subregions have been mapped (Fig. 8). These recombination points all map near to the E_β gene within a 9.8-kb segment of DNA. Indeed, serological and peptide map analyses suggest that the recombinational event in B10.GD mice occurred in the E_β gene[34,36]. This result is in agreement with our chromosomal mapping studies using restriction enzyme site polymorphisms. We carried out several types of control experiments. First, in certain cases we analysed doubly recombinant strains of mice which had been generated by genetic crosses between one of the above recombinant congeneics and a new parental strain. In each case where the *I*-region recombinant haplotype was retained, the same polymorphic restriction fragments were observed as in the original parental strains (Table 1, Fig. 6). Second, critical strains B10.A(3R), B10.A(5R), B10.S(8R), B10.S(9R) and B10.HTT were obtained from other laboratories (D. Murphy and C. David) and gave the same results as the identical strains raised in our colony (J.F.). From a comparison of the lengths of those restriction fragments (Fig. 6) which span the recombination points in the appropriate recombinants with the maps of the parental haplotypes in Fig. 8, it is clear that the recombination events have occurred without any major duplication or deletion of DNA sequences. For example, in Fig. 7*c*, a 12.2-kb *Eco*RI fragment is detected in B10.A(3R) and B10.A(5R) and a 6.2-kb fragment is found in B10.A(4R) with probe 4 which is derived from the large intervening sequence in the E_β gene. As can be seen from Fig. 8, these *Eco*RI fragments span the recombination points in the recombinants. The sizes of these *Eco*RI fragments support the

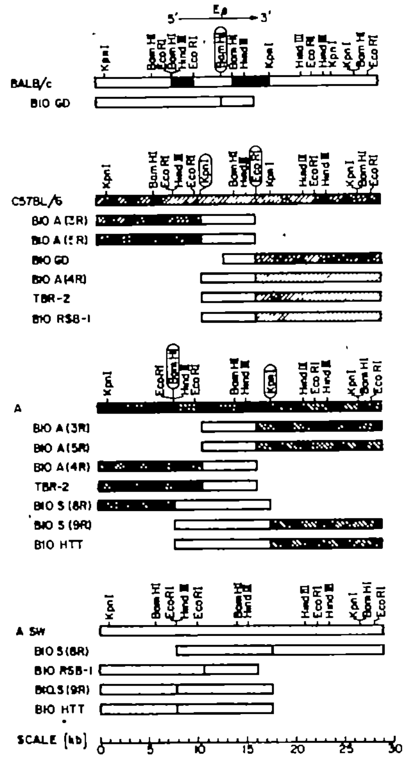

Fig. 8 Partial restriction maps for 27 kb of DNA around the E_β gene in mouse strains of *d*, *b*, *k* and *s* haplotypes. These maps indicate the regions where crossing-over occurred in nine independently generated recombinant congeneic strains. The restriction maps for the four mouse strains were obtained by Southern blot analyses of single and double digestions of mouse liver DNAs with the indicated enzymes using probes 3, 4 and 5 as hybridization probes (see Fig. 2 for the location of these probes). Compared with Fig. 2, the map for BALB/c shows only the restriction sites mapped by Southern blotting. Maps obtained by Southern blotting might not reveal all sites for the enzymes used since sites outside the fragments detected with the hybridization probes are not seen. This limitation of the method, however, does not affect any of our present conclusions. The location and maximal size of the 5' and 3' exons of the E_β gene are indicated in the BALB/c map by black boxes (see Fig. 2 legend for a discussion of the organization of this gene). Those regions of the four chromosomal DNA segments that are present in the nine recombinant congeneic mouse strains according to our analyses, are indicated by appropriately marked bars below the restriction maps. The grey boxes indicate the regions in the recombinants where the crossing-over has occurred and which cannot be assigned at present to either parent because of the lack of polymorphic restriction sites. Polymorphic restriction sites confining the regions of recombination are circled.

hypothesis that the recombinants have been generated by a homologous crossing-over event.

The recombinational events in the nine independently generated recombinants analysed could all have occurred at precisely the same site. As discussed above, we are in the process of subcloning several of these recombinant regions to identify in molecular terms their precise points of recombination. These observations suggest that in the *I* region, recombinational events are not random but rather occur in certain highly localized regions. This obviously has important implications for any attempts to correlate genetic maps that are determined by recombinational analyses and molecular maps determined by direct cloning. For example, the A_β and the E_α genes are by recombinational analyses about 0.1 centimorgan apart[2]. As the mouse genome is 1,600 centimorgans long and contains about 3×10^6 kilobars pairs, 0.1 centimorgan corresponds to about 200 kb (if on the average recombination is random throughout the mouse genome). We have now established directly that the A_β and E_α genes are separated by about 85 kb of DNA (Fig. 2) and that all the recombinational events analysed in this region occurred within 9.8 kb of DNA. One wonders if genetic maps for other regions of the eukaryotic genome will show similar recombinational preferences. In particular, it will be interesting to determine whether there are other hot-spots of recombination within the major histocompatibility complex, as for example between the *I–E* subregion and *S* region or between the *S* and *D* regions—two sites where many cross-overs have been mapped.

The future

The cloning of the *I* region will permit the precise identification of genes involved in immune responsiveness and other phenotypic traits encoded by this region. We will be able to use the techniques of gene transfer and *in vitro* mutagenesis to determine which genes control specific traits and how they function to regulate these traits. The cosmid clones encompassing the *I* region can be used to determine whether other previously undetected *I*-region genes are expressed in cells that control various aspects of the immune response such as B cells, T cells or macrophages. The detailed knowledge of the *I–A* and *I–E* loci will be of great value in the analysis of the human *I* region at the molecular level. Finally, it is clear that the genetic map of the *I* region can now start to be replaced with a molecular map which localizes precisely the genes encoding the various types of class II polypeptides.

We thank Elizabeth Gibb for technical assistance, Joan Kobori for a gift of probe 3, Bernita Larsh for the preparation of the manuscript, and all members of the Hood group for stimulating discussions. We also thank P. Singer and J. Klein, D. Murphy and C. David for various congeneic mouse strains. M.S. was supported by the Deutsche Forschungsgemeinschaft and by a Senior Lievre Fellowship from the California Division of the American Cancer Society (S-48-82). J.M. is a postdoctoral fellow of the Arthritis Foundation: J.F. is the recipient of an American Cancer Society Faculty Research Award. The work was supported by grants from the NIH.

Convective cloud merging and its effect on rainfall

D. A. Bennetts, M. J. Bader & R. H. Marles

Meteorological Office, Bracknell, Berkshire RG12 2SZ, UK

An important aspect in the study of cumulonimbus convection is the identification of situations that lead to intense rainfall. We examine here one such situation in which two initially separate clouds interact and merge. The process is found to depend on the variation of wind with height, the relative stage of development of the two clouds and their initial separation. A numerical simulation is described in which merging is shown to increase the total surface precipitation by a factor of four.

Simpson *et al.*[1] investigated the development of merging cumulus when the two separate clouds were initially two or three cloud diameters apart. They suggested that new growth could take place above colliding gust fronts formed by the downdraughts from each cloud. Large accumulations of rainfall resulted from the increased size and duration of the cloud complex. Here an alternative mechanism of merging is considered in which the amount of rain is increased by enhancing the rainfall rate[2]. The work is a development of an idea discussed by Orville *et al.*[3] in which two separate cumulonimbus clouds grow in close proximity, closer than that necessary for the merging process described by Simpson *et al.* Under favourable combinations of vertical wind shear, cell separation and relative cloud development, the cloud motion fields (as opposed to the downdraughts) interact and the clouds merge to form a single entity.

The effects of this type of merging should be evident in the rainfall characteristics of a field of convective clouds, particularly if those clouds are similar in size and growing in uniform conditions. On such occasions most clouds might be expected to have similar rainfall, but a few, growing sufficiently close, would merge, the consequent enhancement in rainfall rate being dependent on the effectiveness of the merging. Such rainfall characteristics have been observed using a weather radar[4,5]. The peak rainfall rate of most of the clouds fell within

Table 1 A comparison of the water budgets of the single cell and merged clouds

		Single cell	Merger	Difference merger − single
1	Total available condensed cloud substance CN	3.8×10^8 kg	10.12×10^8 kg	+33%
			(Fractions per unit CN)	
2	Total precipitation generated within the cloud comprising of	0.55	0.61	+0.064 (+12%)
	a, accretion of cloud water by rain and hail	0.23	0.31	+0.080 (+35%)
	b, other processes (such as autoconversion of cloud water to rain, sublimation of cloud ice to graupel)	0.32	0.30	−0.016 (−5%)
3	Precipitation evaporated below cloud base	0.47	0.39	−0.086 (−18%)
4	Net precipitation reaching the ground as rainfall	0.07	0.22	+0.15

Water budgets: 1, The net condensed cloud substance (CN): the percentage change in the third column is calculated using CN from two single cells. 2, The total amount of precipitation produced within the cloud together with a breakdown of the physical processes involved. 3, The evaporation. 4, The surface rainfall, that is the total amount produced minus that evaporated. All values in 2, 3 and 4 are expressed as fractions of CN.

the range 5–15 mm h^{-1}, but up to 30% had a much higher rainfall rate, in the range 30–100 mm h^{-1}. It has been suggested that the second group might have resulted from merging. To investigate this, both single and merging clouds have been simulated with a tuned three-dimensional numerical model[6] using representative thermodynamic and dynamic data[5]. Details of the microphysical and turbulent parametrization schemes, together with the model boundary conditions, are given in ref. 6, but for brevity are omitted here.

Figure 1 shows the early development of two clouds, separated in distance by 7 km and in time of initiation by 6 min. Each shows a vertical section through the centre of the cloud parallel to the direction of the mean wind. At a simulated cloud time of 12 min the motion field of the larger cloud has not developed sufficiently to influence the growth of the other and both clouds lean to the right, as would be expected in the prevailing conditions. By 16 min the clouds have merged perceptibly. Large ice particles begin to form in the more mature cloud and, by 20 min, their concentration has reached 0.05 g per kg and their fall speed, in still air, is ~6 m s^{-1} (ref. 6). At this stage they can be considered as 'embryo precipitation particles'.

The instantaneous velocity vectors are evaluated relative to the mean speed of the larger cloud which corresponds to the wind at 725 mbar (~3 km above the surface) in the undisturbed air. Relative to this frame of reference the inflow and outflow are clearly evident. The clouds move at slightly different speeds because of their different size (which affects their interaction with the undisturbed flow), and their mutual interaction. As a result, the region of high liquid water content (>2 g per kg) in the lower part of the right hand cloud is advected towards the left (relative to the frame of reference defined above), and by 24 min (Fig. 1*d*), is positioned so that subsequently the precipitation falls through it, the growth of the precipitation thereby being greatly enhanced by accretion of numerous small water droplets. This process, whereby precipitation generated in one cloud is augmented as it passes through another, is similar to that encountered near high ground[7] where precipitation generated from frontal cloud grows by accretion of orographically induced cloud which forms lower down, just above the hill.

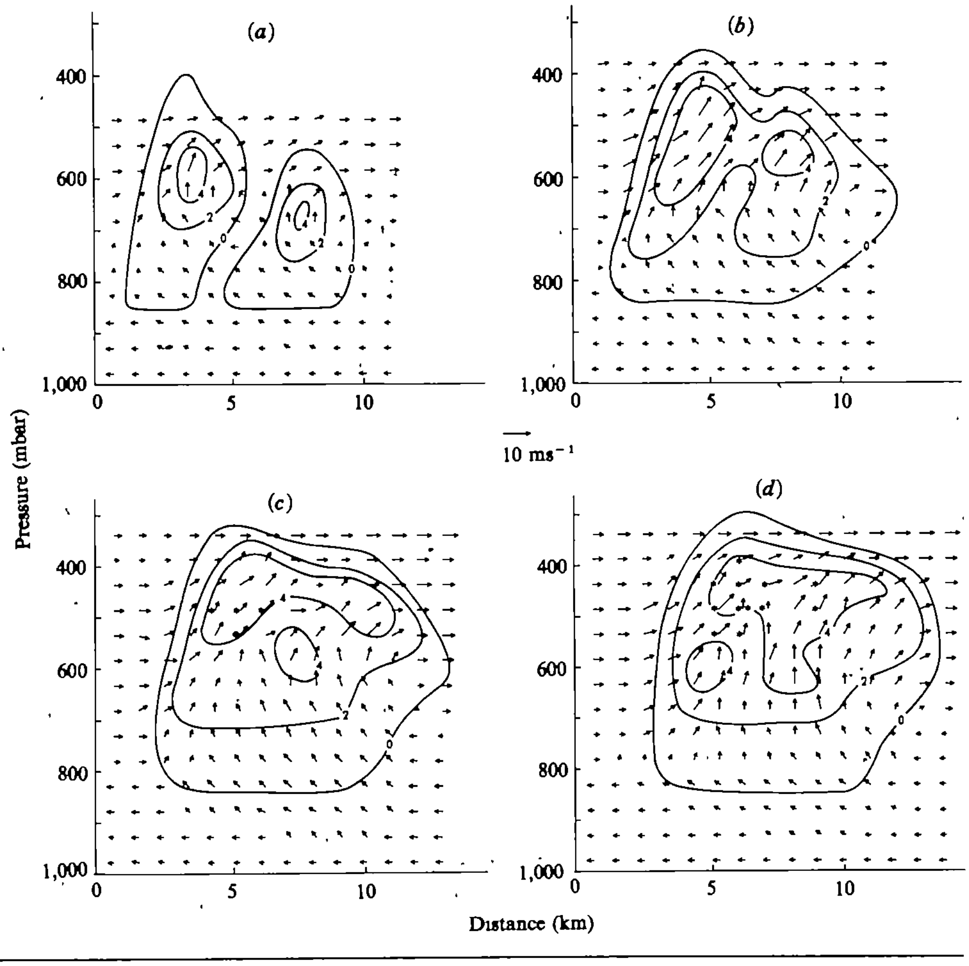

Fig. 1 Distribution of cloud content (water and ice) in g per kg within the clouds at a simulated time of: *a*, 12 min; *b*, 16 min; *c*, 20 min; *d*, 24 min. Arrows denote wind velocities in the plane of the diagram relative to the mean speed of the left hand cloud. The presence of rain (•) and hail (*) is also indicated.

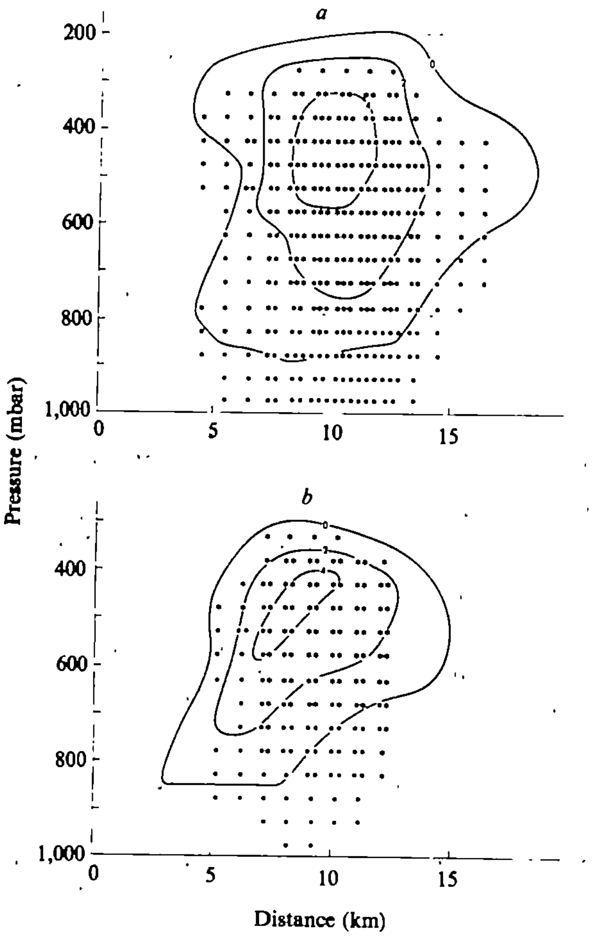

Fig. 2 Distribution of rain (•), hail (*) and cloud substance (water and ice) at a simulated time of 36 min within: *a*, the merged cloud; *b*, the single cell. Isopleths of cloud content are in g per kg. The number of symbols in each group represents concentrations of <0.5, 0.5–2.0 and >2.0 g per kg. These approximate to rainfall rates of <8, 8–44 and >44 mm h^{-1} respectively.

The second region of high liquid water content low down on the left hand side of the cloud in Fig. 1*d* cannot influence the growth of the precipitation by accretion because it is in an unfavourable position. During the subsequent development it rises to the top of the cloud to provide a continuing supply of precipitation embryos. A later stage in the development when merging is complete is shown in Fig. 2*a*. There is a high concentration of rain and hail in the centre of the cloud and the maximum modelled instantaneous rainfall rate at the surface (1,000 mbar) is ~100 mm h^{-1}. Comparison between this and a modelled single cell cloud (Fig. 2*b*) growing in the same environment shows that the merged cloud produces ~4 times more total surface precipitation than two individual clouds growing separately, and there is a 10-fold increase in the maximum instantaneous surface rainfall rate. (Both the merged and single clouds have a similar size and structure in the cross-shear plane.)

The rainfall characteristics of both simulated clouds are shown in Fig. 3 together with observations[5] from radar. The observed rainfall rates, averaged over 4 km^2, are the highest within the radar echo of the cloud; the modelled rates are the means of the four grid values (each 1 km^2) centred on the simulated peak surface rainfall. Both sets of values are subject to some uncertainty. Calibrated radar observations are generally considered to be representative to within a factor of ~1.5 but it is difficult to be as precise in estimating the errors in the numerical model. There are uncertainties in the parametric representation of the microphysical and turbulent diffusion processes as well as in the effects of the lateral boundary conditions. An attempt has been made to 'tune' the model[6] to reduce these uncertainties but it would be unwise to suggest that the predictions had an accuracy greater than a factor of 2, although a direct comparison between simulations has the merit that many of the uncertainties at least remain constant. In consequence, the agreement between observed and modelled peak rates is fortuitously close, but there is no doubt about the difference in rainfall rates between the single cell and merger clouds.

Comparison between the two simulations shows that more rain reaches the ground from the merger because more precipitation is produced by accretion within the cloud and there is less evaporation below cloud base. The relevant quantities are shown in Table 1. The production of precipitation by accretion and loss by evaporation are expressed as fractions of the mass of cloud substance (water and ice) available for the production of precipitation. This quantity (CN) represents the difference between the cloud substance condensed and that evaporated at the cloud boundary.

The total precipitation produced per unit CN within the merged cloud is 12% greater than that within the single cell because a higher proportion of cloud water is accreted in a merger. The proportion of precipitation generated by other microphysical processes is similar in both clouds; in fact, there is slightly less in a merger because the cloud water content has been depleted by accretion. In addition, the amount of precipitation lost by evaporation below a merger is 18% less than that below a single cell. This results in the fraction of precipitation reaching the ground from the merger being three times greater than that from the single cell. However, CN in the merger is more than twice that in the single cell and, expressed in absolute terms, the mass of precipitation reaching the ground from the merged cloud is four times that from two single cells.

The increased efficiency of precipitation production within the merger can partly be explained by its increased size. The relevant parameter is the horizontal displacement of a precipitation particle as it falls compared with the 'width' of the cloud. This determines the proportion of time spent by the particle accreting water inside the cloud to that spent evaporating outside it. The efficiency also depends on the dynamic interaction of the clouds which determines the relative position of the precipitation and regions of high liquid water content.

At present the relative importance of cloud size and the dynamical effects of merging are not known. However, supple-

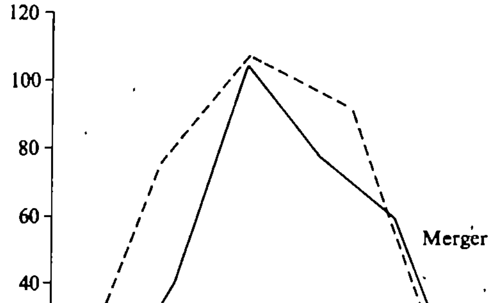

Fig. 3 Simulated and observed rainfall rates for merged and single cell clouds. The dashed curve labelled 'single' depicts observed rainfall rates that were typical of the smaller clouds and the dashed curve labelled 'merger' the rainfall rates of the largest cloud observed[5]. The largest was chosen as the numerical simulation (solid line) shows the results of the most efficient merger achieved. Note that, in the text, comparisons are between mergers and two single cell clouds. The simulation shown here labelled 'single' (solid line) represents one single cell cloud to enable direct comparison with observations.

mentary numerical simulations have shown that merging can both increase the surface rainfall by a factor of four, and decrease is by ~40%. A reduction in rainfall can occur when the wind field of the primary cloud dominates that of the secondary which, in the limit, is drawn into the updraught of the primary cloud before it has grown past its embryonic stage. Consequently the large variability often observed in convective precipitation[5] can be accounted for even without considering the natural environmental variability that is almost certainly present within any air mass.

Cyclic thermal transformations in caesium graphite

A. R. Ubbelohde & I. Drummond

Imperial College, Department of Chemical Engineering and
Chemical Technology, London SW7 2BY, UK

Various physical properties can yield novel information about effects of texture of a graphite, on the detailed course of any thermal transformation of a graphite intercalate, when it is subjected to cyclic changes of temperature including a lambda peak. Using a DSC calorimeter with an imposed temperature change of 10 K min^{-1}, we have found a novel transformation in caesium graphite CsC_8 around 250 K. We show here that fine details appear to be sensitive to the texture of the graphite used.

When electron donor or electron acceptor molecules intercalate into graphite, this pushes the carbon hexagon sheets apart by several nanometres. Any occasional defect-bonding between neighbouring parallel carbon hexagon sheets becomes stressed by this enforced separation, and in near-ideal ordered graphites 'rogue bonds' between the sheets may even snap. On lessening this stress by removing the intercalated molecules, in favourable cases the rogue bonds may not reform. Planned sequences of intercalation and removal might thus in principle be made a means for permanently improving the quality of well ordered graphites. Unfortunately, the graphites and pyrographites available in the early experiments were not sufficiently well ordered to test sequences of intercalation and removal adequately. It was found that a proportion of the intercalated molecules remained 'locked-in', as so called 'residue compounds'[1]. Use of better oriented graphites, as prepared by subjecting pyrographites to stress annealing[2–4], gives a less confused response to sequences of intercalation and removal of the intercalated molecules, particularly when optimum behaviour of the lamellar framework is attained, by careful quality selection[5] of highly oriented pyrolytic graphite (HOPG).

When a graphite intercalate undergoes one or more thermal transformations on traversing a range of temperatures, even more gentle stresses can be imposed through cyclic changes of temperature; for example, there are changes of structure but no changes of composition in cycling the temperature around a lambda point. With this in view, various thermal transformations in graphite intercalates are being studied. These present some novel features in the chemical physics of solids, where previous research has been largely restricted to three-dimensional structures. Quite often a choice can be made between several different physical properties for study in relation to the thermal transformation. For example, the lambda transformation in graphite nitrates and deuterates with a peak temperature around 252 K has been followed in cyclic temperature changes using observations of changes in thermal expansion, lattice structure, electrical resistivity, thermal e.m.f., and pulsed NMR[6–9]. Because of the extremely high anisotropy of these compounds, as the temperature is varied the sharpness of peak change in any one layer may differ notably from the (often much lessened) sharpness of the correlation between neighbouring layers. In the limit, each layer of intercalate might be effectively independent of even the nearest neighbour layers; effectively two-dimensional thermal transformations would be of considerable theoretical importance as well as practical interest. But in practice, at least weak correlation of molecular behaviour can generally be observed between neighbouring layers, up to (say) five away. These considerations make it desirable whenever feasible to choose physical properties which can be conveniently studied parallel and perpendicular to the layers, independently. For example, to enlarge the possibilities, methods of measuring resistivity changes perpendicular to the layers have recently been improved[5].

Knowledge of the enthalpy and entropy changes provides important background information for interpreting any of the other physical measurements on transformations in intercalation compounds. A 'rate of enthalpy change' calorimeter has recently become available which has the advantage of requiring only a few milligrammes of substance. Despite certain limitations, such as the rather fast changes of temperature that must be used, this calorimeter has given interesting preliminary information about graphite nitrates[10]. It has now been used with caesium graphites. Both the first stage and second stage intercalates have been studied, but for simplicity the present report deals principally with the first stage intercalate CsC_8. Unexpectedly, calorimetry reveals a thermal transformation in the temperature range around 250 K, which has not been hitherto detected either in resistivity studies, or detailed X-ray diffraction measurements[9] in CsC_8.

Our general methods followed regular two-bulb preparative techniques. To permit comparisons between graphites of different textures each preparation exposed four different specimens of ~25 mg side by side to the caesium vapour, in conditions appropriate for obtaining the first or the second stage intercalate. After completion of intercalation the specimens were covered with non-reactive petroleum jelly[11]. It was verified that *per se* this film of jelly (which facilitates handling particularly after intercalation) makes a negligible contribution to the calorimetric anomalies now reported: interestingly the jelly showed a very weak glass-type transformation at considerably

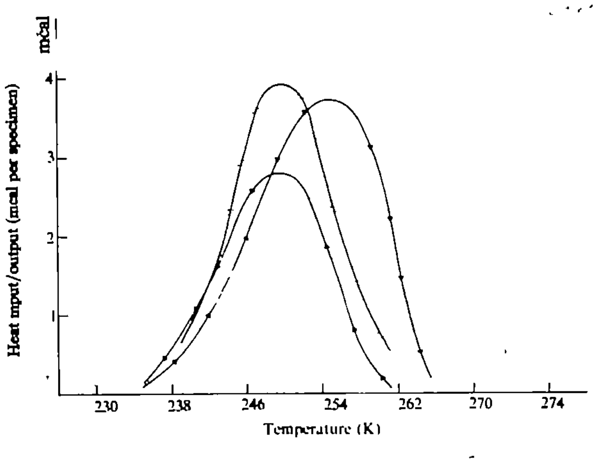

Fig. 1 Heat input/output for two different specimens of CsC_8. For HOPG (▼) the direction of temperature changes imposed follows the arrows. For Ticonderoga (natural) graphite (☐) only the cooling curve is shown.

higher temperatures, but this could not be shown on the scale used for Fig. 1.

Following earlier indications of its importance (see ref. 12) in the present studies particular attention was paid to the textural quality of the graphites used for intercalation. Two graphites of different origins were used. Figure 1 refers to stress-annealed pyrographite carefully selected by us from samples of HOPG (provided by A. Moore of Union Carbide), and to a piece of Ticonderoga graphite broken off from a fairly large specimen of this geological deposit. As anticipated, the thermal behaviour of CsC_8 although prepared under identical vapour pressure of caesium differed in fine detail, depending on which graphite was intercalated, and whether the temperature was rising or falling through the transformation, roughly between 238 and 262 K (Fig. 1). The origin of rate dependent differences between the two samples cannot yet be pinned down with certainty. Rate-controlled input or abstraction of heat is used with the present type of calorimeter; so far, only heat transfers accompanying temperature changes of 10 K min^{-1} have been used exhaustively. With such a simple type of intercalate as atoms of caesium, many solid state processes should be too rapid to be distorted by the rates of change of temperature imposed on the calorimeter. Provisionally, the findings suggest some kind of order/disorder, with details controlled by the texture of the carbon-hexagon layers in the two varieties of graphite studied; suggestions have been made with reference to transformations in CsC_{24} (ref. 9) which appear to be related to the thermal transformations now reported in CsC_8.

The magnitude of the thermal transformation is also noteworthy. Approximate integration of the calorimetric data indicates a total enthalpy change of about 26.7 cal per g atom, with an entropy change of only about 0.1 e.u.

Observations that the texture of the graphite can have such marked influence on the fine detail of thermal transformations of intercalates emphasize the need for graphites of better quality than any yet available, when seeking to establish unusual two-dimensional effects such as phonon–electron interactions and superconducting transitions.

Note that although the choice of intercalates with such strong electron donor character as caesium for the present research has been made because they present a special theoretical interest, they also enhance the practical difficulty that these intercalate atoms are highly reactive chemically. Our experience with this novel calorimeter is limited. Despite all the precautions taken against the intrusion of reactive species other than graphite, and caesium, part of the interesting non-reversibility which may be seen in Fig. 1, could be due to some permanent loss of caesium in each cycle, by combination with other intruder molecules. However, a dominant role of the texture of the graphite, in determining fine differences between different specimens, seems certain.

Pu, ^{241}Am and ^{137}Cs in soil in West Cumbria and a maritime effect

R. S. Cambray & J. D. Eakins

Environmental and Medical Science Division, AERE Harwell,
Oxon OX11 0RA, UK

Discharges to the Irish Sea from Sellafield (formerly Windscale) in Cumbria in the period 1957–79, included about 16,000 Ci of Pu α activity and 800,000 Ci of ^{137}Cs, in addition to other actinides and fission products[1–6]. Most of the ^{137}Cs in the sea remains in solution whereas ~95 % of the Pu is removed to sediments[7]. To ascertain whether any of this discharged material was being transferred back to land, samples of soil were taken along two transects normal to the Cumbrian coast and extending up to 20 km inland. We report here that Pu and Am deposits decrease with distance inland and correlate with deposits of marine-derived sodium. An enrichment of actinides in seaspray relative to seawater is required to account for the observed deposits.

Samples from the first transect, between St Bees and Ennerdale, were collected in May 1977 and from the second, between Nethertown and Newlands, in July 1979. The locations of these transects and the individual sampling sites are shown in Fig. 1. Soil was taken from apparently undisturbed sites to a depth of 15 cm using core tubes of 3.8-cm diameter. Three cores were taken at each location, combined, dried at 105 °C, ground to a particle size of $< 150\ \mu m$ and homogenized. Approximately 100 g of each bulked sample were taken for analysis by γ-ray spectrometry, using lithium drifted germanium detectors. ^{137}Cs was determined from the spectra by least squares fitting using automatic data processing[9,10]. Plutonium was determined on 70 g samples by an acid leaching technique[11], using ^{242}Pu as an internal tracer. The amounts of ^{238}Pu and $^{239+240}$Pu in electrodeposited sources were determined by α spectrometry. Soils from the Nethertown transect were also analysed for ^{241}Am by radiochemistry and α spectrometry, using ^{243}Am as a tracer. The analytical results are presented in Table 1, radionuclide concentrations being expressed as deposits per cm^2 to a depth of 15 cm.

To evaluate the results, the deposit of radionuclides in soil due to fallout from distant nuclear weapons must be considered. The accumulated deposit depends mainly on rainfall[12] and latitude[13]. Results from a nationwide survey[14] have shown that, in Britain, the ^{137}Cs deposit (to a depth of 15 cm) is ~ 7.5 pCi cm^{-2} per m of rain. The $^{239+240}$Pu deposit is ~ 0.14 pCi cm^{-2} and that of ^{238}Pu, including a contribution from a satellite burnup[15] in 1964, is ~0.006 pCi cm^{-2}. The fallout baseline for ^{241}Am is not so well established. However, the mean ratio of ^{241}Am to $^{239+240}$Pu on the Nethertown transect between 10.9 and 20.5 km inland is 0.23, a value which agrees with the global estimate of Krey *et al.*[16]. This ratio suggests a ^{241}Am deposit from the testing of nuclear weapons of ~ 0.032 pCi cm^{-2} per m of rain. The weapons fallout contribution at each site has been estimated from the mean annual rainfall

10	—	—	—	—	—	20.5	2,130	19	0.02	0.41	0.10

Values are pCi cm^{-2} to a depth of 15 cm.
The uncertainties, $2\sigma_\alpha$, on the above results associated with counting statistics are ~30%, 25%, 10% and 15% for ^{137}Cs, ^{238}Pu, $^{239+240}$Pu and ^{241}Am respectively. The variability of sampling, $2\sigma_s$, is generally <25%.

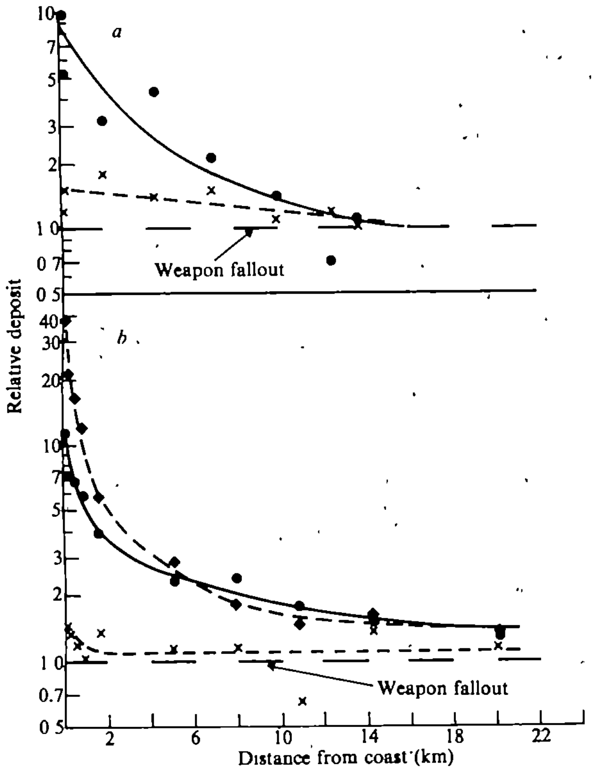

Fig. 2 Deposits of ^{137}Cs(×), $^{239+240}$Pu (●) and ^{241}Am (◆) in soil, relative to fallout from nuclear weapons tests. *a*, St Bees Transect (1977); *b*, Nethertown Transect (1979).

using data published by the Meteorological Office[17]. In Fig. 2*a* the deposits of ^{137}Cs and $^{239+240}$Pu at each site on the St Bees transect have been plotted, as a ratio to the estimated deposit due to fallout, against distance inland. Figure 2*b* shows similar results for the Nethertown transect, including data for ^{241}Am.

The $^{239+240}$Pu deposit at the coast on both transects is about a factor of 10 greater than expected from nuclear weapons fallout. As may be seen from Table 1, the ratio ^{238}Pu/$^{239+240}$Pu falls with increasing distance from the coast. At the coast, the value of this ratio is characteristic of the highly irradiated material discharged from Sellafield[5,6]. The relative deposit of ^{241}Am near the coast on the Nethertown transect is greater than that of $^{239+240}$Pu but it decreases in a similar way with distance inland. In contrast, the deposit of ^{137}Cs in both transects is only slightly enhanced at the coast and rapidly becomes indistinguishable from nuclear weapons fallout.

Figure 3 shows the excess deposits of ^{238}Pu and $^{239+240}$Pu on the St Bees transect plotted against distance from the coast. Included in Fig. 3 are values for the annual sodium deposit derived from measurements at several sites in the United Kingdom[18,19] and in Holland[19]. The latter agree with data reported elsewhere[20]. It is apparent that the slopes of the three lines are broadly similar, demonstrating a correlation between Na and Pu deposition. This, together with the general shape of the deposition curves, is taken as good evidence that the excess Pu is of maritime origin and associated with seaspray. A similar maritime effect has been reported[21] in the coastal region of Normandy, France, near the fuel reprocessing works at La Hague.

The excess deposit of $^{239+240}$Pu in soil at St Bees is 1.2 pCi cm^{-2} and the annual Na deposit at the coast (10^4 μg cm^{-2} from Fig. 3) is equivalent to $\sim 10^{-3}$ l cm^{-2} of seawater. Approximately 70% of the Pu discharged to sea between 1957 and 1977 was discharged after 1970, when the concentration of $^{239+240}$Pu in filtered inshore seawater was reported[7] to be ~0.5 pCi l^{-1}. The expected annual deposit of $^{239+240}$Pu from seaspray at the coast would therefore be ~ 5×10^{-4} pCi cm^{-2}, or 3×10^{-3} pCi cm^{-2} over a 6 yr period. An enrichment factor of 2 or 3 orders of magnitude in seaspray is therefore required to account for the excess $^{239+240}$Pu in soil along the St Bees transect. An analysis of ^{241}Am deposits in the Nethertown transect indicates that a similar enrichment factor is required to account for the deposition of this radionuclide. However, the deposition of ^{137}Cs in both transects can be accounted for by levels in bulk seawater with no evidence of enrichment.

Possible mechanisms which may be involved in the transfer of radioactivity from sea to land are: (1) direct suspension of the sea surface by the wind in the form of spray; (2) conversion of the sea surface material into aerosol by bubble bursting[22,23];

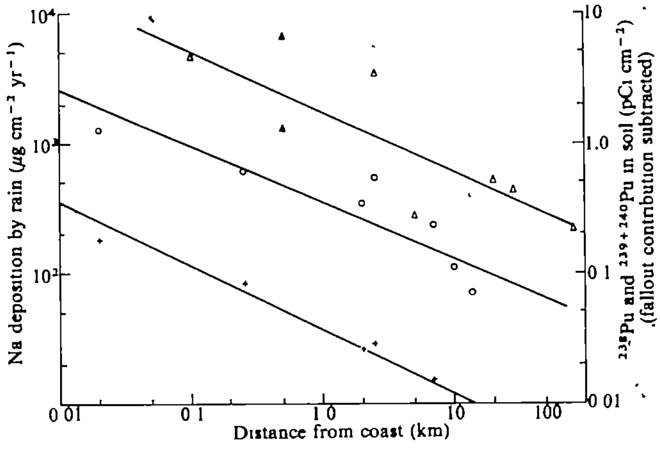

Fig. 3 Deposition of Na(△), ^{238}Pu (+) and $^{239+240}$Pu (○) versus distance from the sea (1977).

(3) injection of seawater and suspended sediment into the air by waves breaking in the surf zone; and (4) movement of sediment to intertidal regions with subsequent resuspension by wind. Of themselves, the results do not favour any one of the above mechanisms but the apparent existence of an enrichment effect for Pu and Am in seaspray, and its absence for ^{137}Cs, suggests that the mechanism may be related to the sediment in seawater rather than to material in solution. Perhaps the most likely mechanism is the production of high concentrations of suspended particulates in the surf zone produced by the action of breaking waves and the consequent injection of particulates into the atmosphere with spray.

To put the observed values in perspective in relation to hazards they can be compared with some proposed limiting values. The highest observed deposit of Pu was ~2 pCi cm^{-2} in a 15 cm depth of soil. This is more than a factor of 1,000 below the Generalized Derived Limit for Pu in well-mixed soil as specified by the National Radiological Protection Board[24].

This work was supported in part by British Nuclear Fuels Ltd and the Department of the Environment.

CH_4, H_2, CO and N_2O in submarine hydrothermal vent waters

Marvin D. Lilley, Marie A. de Angelis & Louis I. Gordon

School of Oceanography, Oregon State University, Corvallis, Oregon 97331, USA

Hydrothermal circulation systems of mid-ocean ridges profoundly influence the chemistry of the oceans and the oceanic crust[1–3]. This has been demonstrated for several major and minor constituents of seawater[4] and trace metals[5]. In addition, several volatile compounds including helium[6,7] as well as methane and hydrogen[8–11] are introduced to the sea floor in concentrations greatly exceeding that of ambient bottom water. We present here our measurements of concentrations of methane, hydrogen, carbon monoxide and nitrous oxide in the hydrothermal vent waters from the Galapagos Spreading Centre (GSC). The relationships of these constituents to silicon were unique for each vent field, with nitrous oxide at East of Eden being the only instance of negative correlation. These gases could serve as important energy sources, in addition to hydrogen sulphide, for the chemosynthetic bacteria which support the extensive and diverse animal population living in these environments[12,13].

Two principal types of hydrothermal vents have been discovered and studied to date. At the GSC (0°48′ N, 86°0.8′ W) warm (7–23 °C) water flowed from gaps, or 'vents', between basaltic pillows at linear flow rates of the order of cm s^{-1}; similar vents have been found at 21° N on the East Pacific Rise[14,15]. The second type, found at 21° N but not at the GSC, had hot (~350 °C) water flowing from sulphide 'chimneys' at rates of m s^{-1}. The data presented here represent hydrothermal water samples collected using the research submersible, *Alvin*, from three separate vent fields at the GSC in March 1979.

Corliss *et al.*[1] showed that the silica concentration in the GSC vent samples defined a single linear relationship with temperature and, owing to uncertainties in the temperature measurements, provided a better measure of the degree of mixing between the hydrothermal end-member and ambient seawater than did temperature. We therefore present the GSC gas data relative to dissolved silica in Fig. 1.

$CH_4/^3He$ and $H_2/^3He$ ratios for these vents are compared with those from sites along the East Pacific Rise in Table 1. The 21° N hydrothermal end-member is chemically very similar to the Galapagos end-member estimated by magnesium and silica geothermometry[3].

If the hydrothermal end-member solutions were in equilibrium with the quartz–fayalite–magnetite (QFM) buffer then they should contain approximately 400 mM hydrogen at 350 °C and 500 bar (ref. 18). This would imply $H_2/^3He$ ratios of the order of 10^{10} which are orders of magnitude higher than those observed (Table 1). Either the QFM buffer system does not control the H_2 concentration in these solutions or significant H_2 sinks, such as reduction of CO_2 and sulphate, occur in the ascending fluids. Hydrogen is an excellent energy source for several species of chemosynthetic bacteria[19], hence these reductions could take place abiotically or microbially in the warm water vents.

All of the reduced gases discussed here are produced both abiotically and microbially. Possible abiotic sources of methane, carbon monoxide and hydrogen include injection from the mantle and extraction from basalt by hot fluids. Additional abiotic sources include the reduction of carbon dioxide to form methane and the oxidation of magnetite to haematite,

$$2Fe_3O_4 + H_2O = 3Fe_2O_3 + H_2$$

which has been postulated as the major source of volcanic hydrogen[20]. Nitrous oxide could be produced abiotically by the reduction of nitrate in the descending seawater or by the oxidation of ammonium ascending with the hydrothermal fluids. Ammonium is known to substitute for alkali metal ions in silicate minerals and to be stable at high temperatures and pressures[21]. Nitrous oxide has also been detected in a few volcanic gas samples[22]. Carbon monoxide is a common constituent of volcanic gases[23] and could originate from C–O–H–S equilibria within the magma[24].

An alternative source of these gases in the hydrothermal fluids could be biological production. It is well established that methane, carbon monoxide, hydrogen and nitrous oxide are produced and consumed by microorganisms[25]. Hydrogen can be produced by many microbial species, methane by only one group, the methanogens. Little is known about the production of carbon monoxide by microorganisms but there is evidence that carbon monoxide may be an intermediate in methane oxidation[26].

Nitrous oxide is produced microbially through nitrification and denitrification. Both nitrifying and denitrifying bacteria

0028–0836/82/440048—03$01 00

have been isolated from water samples and animal guts taken from the GSC and 21° N vents (J. Baross, personal communication). Although nitrification and denitrification usually do not take place in sulphide bearing waters such as the vent waters, some bacteria, for example, *Thiobacillus denitrificans*[27], can reduce nitrate to nitrous oxide using sulphide as the electron donor. The nitrogen isotope data[28] indicate that the nitrogen found in vent animals is depleted in ^{15}N and its assimilation into animal tissue must have been preceded by bacterial nitrogen fixation and/or the bacterial assimilation of nitrate or ammonium.

We now consider the observation that nitrous oxide concentrations were found to be enhanced in some and depleted in other GSC vent waters compared with the ambient waters. In the ambient seawater, oxygen and nitrate are the principal electron acceptors involved in biological oxidation. Convective circulation within the warm water vent systems involves penetration of ambient water, thereby supplying these electron acceptors to the resident chemolithotrophic population[1,12,13]. In the process of nitrate reduction, nitrite and nitrous oxide can accumulate and/or serve as intermediate electron acceptors. East of Eden which had the highest observed sulphide to silica ratio (0.853) had the greatest residual potential for reducing electron acceptors. This is consistent with East of Eden nitrous oxide concentrations being lower than those of ambient seawater. Mussel Bed and Rose Garden had lower sulphide to silica ratios (0.072 and 0.232, respectively) and showed net production of nitrous oxide. The determining factor for net production or consumption of nitrous oxide is probably the local redox potential history of a water parcel within the more shallow convection cells of a given vent system.

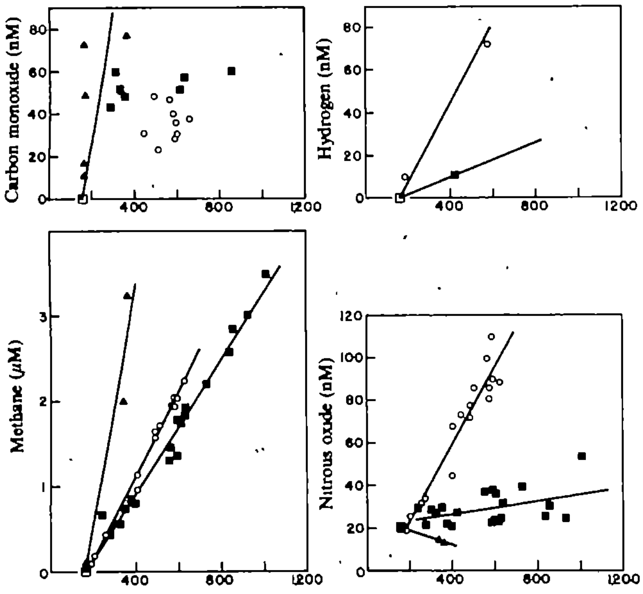

Fig. 1 Reduced gas correlations with silica for the GSC data. The locations and equations for the regression lines shown (not forced through the ambient seawater conditions) are:

△ East of Eden
$CH_4 = -2.23 + 0.0140\,Si$ $N_2O = 25.6 - 0.034\,Si$
○ Mussel Bed
$CH_4 = -0.82 + 0.0049\,Si$ $N_2O = -12.0 + 0.178\,Si$
■ Rose Garden
$CH_4 = -0.63 + 0.0039\,Si$ $N_2O = 19.8 + 0.016\,Si$

The regression line for CO is drawn for the East of Eden data only. Ambient bottom water concentrations were: CH_4, 0.3 nM; N_2O, 20.8 nM; CO, 0.3 nM; H_2, 0.4 nM. Each vent field was characterized by a different range of water temperatures and unique H_2S/Si mole ratios, namely △, 7–8 °C, 0.853; ○, 8–13 °C, 0.072; ■, 8–23 °C, 0.232 (J. Edmond, personal communication). All water samples, except those for H_2 which were taken in PVC samplers, were collected with the pumping system described by Corliss *et al.*[1]. These were subsampled into 125 ml tubular Pyrex flasks with Teflon stopcocks at either end and poisoned to 0.4 mM with $HgCl_2$. A modified version of the gas chromatographic procedure of Swinnerton and Linnenbom[16] was used. The gas chromatograph was equipped with helium ionization and flame ionization detectors.

Table 1 Ratios of hydrogen and methane to ^3He

Vent field	$CH_4/^3He$ (mole ratio)	$H_2/^3He$ (mole ratio)
Galapagos*		
East of Eden	$42.0 \pm 10.9 \times 10^6$	—
Mussel Bed	$14.8 \pm 1.8 \times 10^6$	$0.7 \pm 0.2 \times 10^6$
Rose Garden	$12.4 \pm 1.1 \times 10^6$	0.1×10^6
East Pacific Rise		
21° N, 109° W†	5.0×10^6	$22\text{–}43 \times 10^6$
20° S, 114° W‡	$5.8 - 17.4 \times 10^6$	—

* ^3He data for these GSC vents are not available. We assumed that ^3He in these vents does not differ appreciably from the values obtained by Jenkins *et al.*[7] for the GSC vents sampled during the 1977 expedition. ^3He values for our samples were derived by combining the ^3He-temperature relationship from their Fig. 2 (using the slope which included Garden of Eden) and the temperature-Si relationship for our samples: $T\,(°C) = \dfrac{Si(\mu m) - 28}{59.77}$ (J. Edmond, personal communication).

† Data from ref. 9.

‡ Data from ref. 17.

In addition to the variations seen in reduced gas concentrations among vent fields, systematic variations in several other chemical species have been reported in the GSC vent fields[1,3,5]. These may result from several causes, such as vent field age, differing substrate compositions and differences in water/rock ratios[4]. We hypothesize that the composition of the microbial assemblage in each vent field is characteristic of that field and this is reflected in characteristic production and consumption rates of the gases and other biogenous constituents in the vent water. This hypothesis is supported by the recent discovery that mixed-culture microbial populations, isolated from hot water and chimney rock samples taken at 21° N, can produce hydrogen, methane, carbon monoxide and nitrous oxide and consume methane at 100 °C (ref. 29).

Methane ^{13}C data indicate that the 21° N methane was abiogenic in origin[30] but ^{13}C measurements have not been done on GSC methane. However, because the $CH_4/^3He$ ratio at 21° N is considerably less than that in the cooler GSC vents, and as methanogens are present in vent samples at 21° N (ref. 29), we conclude that methanogens are likely present in the warm Galapagos vents and that part of the methane found in these vents is microbially produced. This is most clearly indicated at East of Eden which had the highest $CH_4/^3He$ ratio (Table 1) yet measured in these vent systems[17]. This conclusion is consistent with the reduced hydrogen levels in the GSC vents; hydrogen would be consumed in the microbial production of methane. Indeed, the question of possible microbial effects on the chemical constituents of submarine hydrothermal systems needs closer scrutiny.

Support for this research was provided by the Office of Naval Research, Marine Chemistry Program, under contract N00014-79-C-0004. We thank the officers and crews of *Alvin*, *Lulu*, and *Gilliss* for assistance, J. Edmond for use of unpublished data, and J. Baross for stimulating discussion throughout, also Erwin Suess and Harmon Craig for helpful reviews.

Palaeomagnetism of volcanic rocks of the Kodiak Islands indicates northward latitudinal displacement

Peter W. Plumley*, Robert S. Coe*, Tim Byrne†, Mary R. Reid‡ & J. Casey Moore*

In the past decade it has become widely accepted that southern Alaska is composed of allochthonous terranes[1–4], but the times of amalgamation and their accretion to North America remain controversial. Palaeomagnetists and geologists generally agree that the Talkeetna superterrane, consisting of the Wrangellia and Peninsular terranes (Fig. 1), was far to the south of its present position with respect to North America in Triassic and Jurassic time[1–4]. This consensus is lost when it comes to the question of the relative position of these terranes in the Tertiary. Previously, limited palaeomagnetic evidence suggested that the Peninsular terrane may have lain substantially south of its present position[4], but the timing of deformational and thermal events and the apparent absence of a Tertiary suture zone argue for a Cretaceous docking of Wrangellia and the Peninsular terrane[5,6]. Here we present new palaeomagnetic results demonstrating that the Kodiak Islands were indeed at a more southerly latitude 62 Myr ago, around 43° N, and discuss the implications of this conclusion.

We sampled the volcanic rocks of the Palaeocene Ghost Rocks Formation exposed along the southeastern margin of the Kodiak Islands (Fig. 1). This turbidite sequence consists of a landward belt with intercalated flows of andesite pillows and a seaward belt including basalt flows. The sedimentary rocks are commonly isoclinally folded and locally grade into zones of tectonic disruption. The volcanic rocks are generally much less deformed and typically form coherent folds. The Ghost Rocks Formation is part of a late Cretaceous to Palaeogene accretionary sequence. The formation is apparently thrust to the north-west against a late Cretaceous trench turbidite sequence[7] and underthrust from the south-east by an Eocene to Oligocene submarine fan complex[8]. Metamorphic prehnite, pumpellyite and laumontite are locally developed[9]. The youngest foraminifera (Palaeocene) and 62 Myr radiometric ages of cross-cutting plutons suggest an early Palaeocene depositional age for the Ghost Rocks Formation.

We drilled and oriented cores of Ghost Rocks volcanics from two regions on Kodiak Island—Kiliuda Bay and Alitak Bay—which are separated by ~80 km along strike. In all, an average of seven cores were collected from each of 29 flows in the two regions. Flow attitudes were almost always obtained from interbedded sediments, and only occasionally from pillow morphology. The Kiliuda Bay sites included locations in both the andesite belt and the basalt belt, whereas the Alitak Bay sites included flows from the andesite belt only.

Stepwise thermal demagnetization proved effective in cleaning the samples from almost all of the flows. Characteristic components of natural remanent magnetization were isolated at temperatures of 300 °C and higher that trended towards the origin on vector diagrams. Considerable improvement in clustering of directions resulted for most flows: the average k increased from 15 to 40 during thermal cleaning. Only 2 of the 29 sites failed to clean up, and one of these was a highly deformed, badly fractured tuff.

Both polarities were found in the flows collected at Kiliuda Bay. Application of the F-test shows that normal and reverse mean directions are not significantly different from antiparallel. These directions also pass the fold test: when correction is made for the tectonic dip of the flows, k increases from 4 in geographical coordinates to 29 in stratigraphical coordinates (Table 1). At Alitak Bay only reversely magnetized flows are present, but these also pass the fold test (Table 1). Thus there is strong evidence that the characteristic magnetization of the rocks pre-dates folding in both areas and probably preserves the original field direction. Even after tectonic correction, however, the mean directions for the two regions are very different (Table 1). The mean declinations differ by 97°, suggesting the regions may have been rotated with respect to each other about a vertical axis. The inclinations also differ from each other by a much smaller, but still statistically significant amount. A likely explanation for this is that the Alitak Bay group of flows spans insufficient time to average out secular variation, although other explanations involving systematic differences in initial dips or in ages of flows between the two regions cannot be categorically ruled out.

The most important palaeomagnetic parameter for regional-scale tectonic interpretation is the mean inclination of the Palaeocene geomagnetic field for the Kodiak Islands. It is reasonable to assume that some sort of average of the data sets for the two regions would give a better estimate of the true inclination than either one of them alone. There are several techniques that have been developed for averaging inclinations only, when declination data are unavailable or should be excluded because of scatter (refs 10, 11, and A. Cox and R. Gordon, in preparation). A straightforward and simple way to do it for this case, however, is to rotate the sets of directions for both regions so that their mean declinations coincide (Fig. 2). Note that the resulting distribution of directions shown in Fig. 2 does not appear particularly non-fisherian (certainly it is not bimodal), which supports the idea that the discrepancy in inclinations between the two regions may be due to incomplete averaging of secular variation. Analysis of the combined

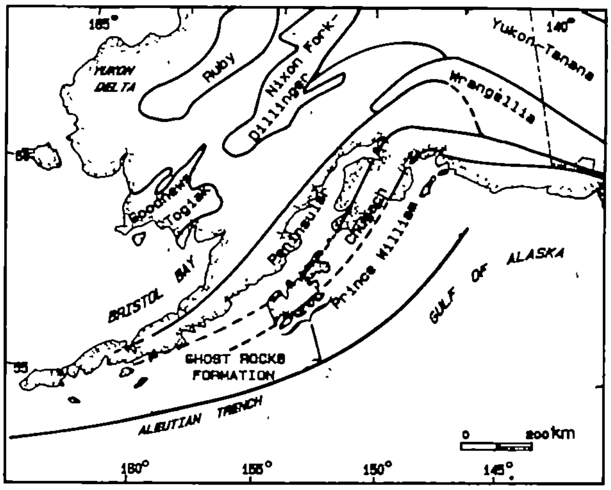

Fig. 1 Generalized terrane map of southern Alaska[14] showing location of the Ghost Rocks Formation.

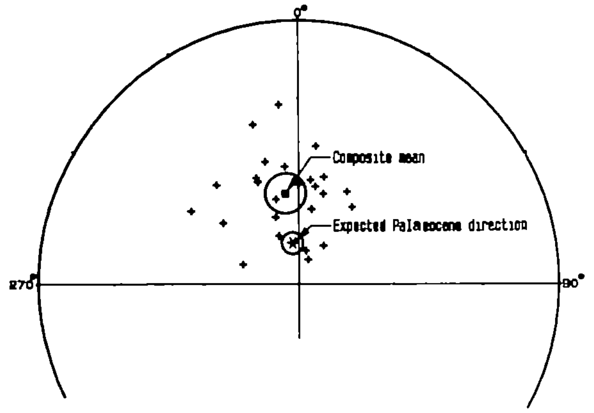

Fig. 2 Site mean directions (reversed inverted to normal): the mean declination for each region (Kiliuda Bay, Alitak Bay) has been rotated (31° clockwise, and 65° anticlockwide respectively) to coincide with the expected Palaeocene declination. Mean of composite data set (■) and expected Palaeocene direction (★) are shown with associated 95% confidence limits.

data set by Fisher statistics[12] gives a mean inclination of 61.4° and 95% confidence limits of ±6.5°. The same mean inclination, within a few tenths of a degree, is obtained by any of the more sophisticated inclination or colatitude statistics referred to above.

As shown in Fig. 2, the mean inclination of the Ghost Rocks volcanics is significantly shallower than that expected for Kodiak if it had been in its present position with respect to North America in Palaeocene time. The corresponding palaeolatitude is 43 ± 9° N, which is significantly less than the expected value of 66 ± 6° N derived from Palaeocene palaeomagnetic data for cratonic North America[13]. Thus the latitudinal displacement of Kodiak with respect to North America that is indicated is 23 ± 11° northward (Fig. 3); any longitudinal displacement is, of course, indeterminate.

The lithology, structural style and geological setting of the Ghost Rocks Formation suggest that it is a Palaeocene subduction complex. On the tectonostratigraphic map of Jones *et al.*[14] (Fig. 1) it is classified as part of the Prince William terrane. However, it is tied to the adjacent Chugach terrane (Fig. 1) by plutons of identical age (60–62 Myr) and composition. The only published palaeomagnetic data from the Chugach terrane are from two Eocene layered-gabbro plutons and a Cretaceous sheeted dyke and pillow basalt complex studied by Grommé and Hillhouse[15]. Although no fold test was described, their results from both sites suggest the Chugach terrane was about 25° south of its present position with respect to North America at these times, in excellent agreement with our results from the Prince William terrane.

The next terrane inboard is the Peninsular terrane (Fig. 1). It is simplest to suppose that the Peninsular terrane formed the backstop against which the late Cretaceous–early Tertiary accretionary complex of the Chugach–Prince William terranes formed, although the geological evidence for this is equivocal. Certainly very similar accretionary processes are occurring there today. The relatively few Tertiary palaeomagnetic data that have been published for the Peninsular terrane are consistent with this idea. In a study of 74 cores of lower Tertiary sediments from four closely spaced localities near Pavlov Bay, Stone and Packer[4] found shallow inclinations that imply low palaeolatitudes comparable to those we have found for the Ghost Rocks Formation.

Table 1 Palaeomagnetic results for Ghost Rocks volcanics

	Dec	Inc	A95	*k*	*N*

Ghost Rocks					
Mean	351.4	61.4	6.5	21.3	25

* Two sites eliminated because of unstable magnetization.

† Two superposed flows with identical NMR eliminated because directions were grossly discordant (>2 s.d. from mean).

Much further inboard, just north of the Denali fault, one finally encounters concordant palaeomagnetic directions. In a study of the Teklanika volcanics, Hillhouse and Grommé[16] have found steep inclinations consistent with the expected palaeocene field. Our own work on Ordovician limestones and a few early Tertiary lava flows in the Nixon Fork terrane 80 km to the west is consistent with their finding[17]. Thus, according to the palaeomagnetic evidence, considerable Tertiary convergence must have been taken up somewhere south of the Denali fault.

Figure 3 shows the band of possible Palaeocene positions for the southern terranes compatible with the palaeomagnetic results for the Ghost Rocks Formation. We have chosen our study to position the southern terranes in the early Tertiary because it is the only one on igneous rocks of well determined age and palaeohorizontal control that passes fold and reversal tests. The locations of the Pacific, Farallon and North American plate boundaries are essentially those of Engebretson (in preparation), who assumes fixed hotspots. The position of the Kula-Farallon ridge is less well constrained because the relevant magnetic anomalies have been subducted.

We favour a Palaeocene position of the southern terranes near to the Kula–Farallon ridge as drawn in Fig. 3 because other evidence suggests that the Ghost Rocks volcanics were the product of a ridge–trench encounter. These lavas are much too close to the subduction zone to be normal arc volcanism[18,19], and their composition, as well as that of the correlative pluton, suggests that they all have a mid-ocean ridge basalt parent[20,21]. Positioning the southern terranes north of the Kula-Farallon ridge allows them to be pushed northward by the movement of the Kula and Pacific plates, rather than being diverted to

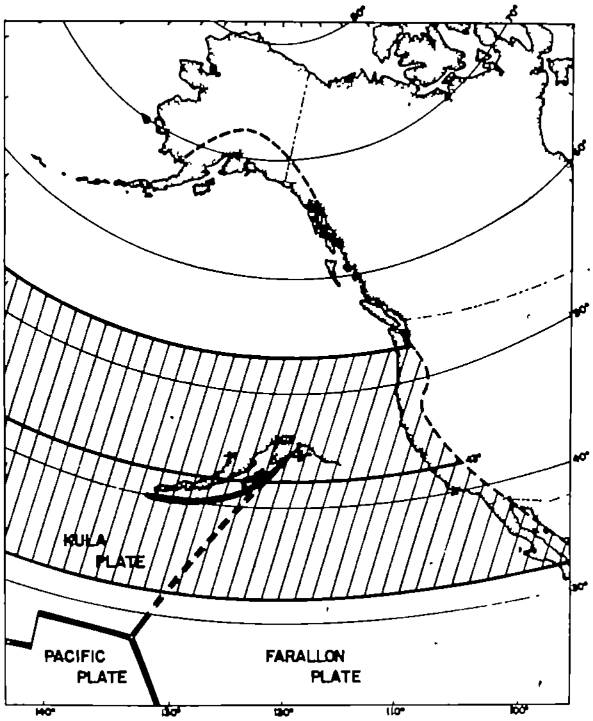

Fig. 3 Palaeocene reconstructiion showing palaeomagnetically inferred latitude for Ghost Rocks Formation, Kodiak, Alaska. Stippled palaeolatitudinal band is the uncertainty with respect to North America at the 95% confidence level. Heavy dashed lines suggest the Palaeocene North American plate margin.

the east by the motion of the Farallon plate. The mystery of the missing Tertiary suture zone in central Alaska required by this reconstruction, however, remains an enigma. These ideas and the data on which they are based will be presented in full detail elsewhere.

^{40}Ar/^{39}Ar dating of pyrite

Derek York, A. Masliwec, P. Kuybida, J. A. Hanes*, C. M. Hall, W. John Kenyon, E. T. C. Spooner† & S. D. Scott†

Department of Physics, and †Department of Geology,
University of Toronto, Toronto, Ontario, Canada M5S 1A7

The precise determination of the age of sulphide ore deposits is one of the most difficult problems in geochronology. This is largely because the very process responsible for concentrating certain metals to an economically significant level also tends to exclude radioactive isotopes from the deposits. It is customary to try to determine the age of mineralization by analysing silicate material presumed to be cogenetic[1]. Because such materials are not always available, and because it is not always clear that the silicates and ore minerals are in fact contemporaneous, we examined the sulphide minerals themselves to see if they contained sufficient potassium and argon for ^{40}Ar/^{39}Ar age determination. Our initial results indicate that this is the case for pyrite from the Geco ore body in northwestern Ontario, Canada.

The direct dating of sulphides with the Rb–Sr technique was attempted by Reesman and Hurley[2]. The results showed promise, but the approach was never pursued. More recently, Luck and Allègre[3] have shown that some deposits may be datable with the Re–Os method. Most promising is the pioneering work on the Rb–Sr dating of fluid inclusions in quartz from a tungsten deposit by Shepherd and Darbyshire[4].

Six pyrite samples have been analysed from the Geco mine, a stratabound and stratiform volcanogenic massive Cu–Zn sulphide deposit[5]. Geco has long been of interest to students of lead isotopes in connection with calculations of the age of the Earth and the chemical evolution of the mantle and crust[6]. The ore body has experienced the Kenoran orogeny[5] and therefore we had *a priori* information on its age. U–Pb and Rb–Sr dating in the area had shown[7] that the last severe regional metamorphism occurred 2,600–2,700 Myr ago. Furthermore, we could add a much more specific age constraint to the ore body when, during mineral separation, we discovered minute amounts of the easily datable biotite in intimate association with sphalerite crystals. A few flecks of these micas were therefore hand-picked for age determination along with the six pyrite samples.

Table 1 Analytical data for Geco biotites (step-heating)

T (°C)	Atmospheric (%)	^{40}Ar* ($\times10^{-5}$ cm^3 STP g^{-1})	*f*(39)	Age (Myr)
Sample GB250†

1,600	2.0	5.21	2.7	2,630±11
Total	0.3	194.35	Integrated age	2,623±6
Standard $(40/39)_s$ = 45.22±0.32				
Mass = 0.0197g				

Decay constants from ref. 11 were used. Errors are ±1σ.
† Only negligible volumes of ^{40}Ar* were released from GB250 below 800 °C.

All samples were irradiated in the McMaster University reactor along with the Zartman hornblende standard[8]. Step-heating runs were performed on two biotite samples whilst the pyrites, because of their extremely low potassium concentrations (5–35 p.p.m.), were fused in single step analyses. The mass spectrometric isotope analysis of the evolved argon was carried out with an MS10 machine. The results are shown in Figs 1 and 2 and Tables 1 and 2. The biotite age spectra in Fig. 1 show excellent plateaus and there is evidence of only minute argon loss in the low temperature fractions. The plateaus are identical within experimental error and indicate that the cooling age of the ore body, after the Kenoran orogeny, is 2,610± 20 Myr. The age spectra indicate that the deposit has undergone negligible heating since then.

The pyrite data are shown in Fig. 2 where ^{40}Ar/^{36}Ar is plotted against ^{39}Ar/^{36}Ar. Such a graphical analysis must, of course, be used as there is no knowing *a priori* what the ^{40}Ar/^{36}Ar composition was in the pyrites at the time they cooled below their argon retention temperatures. The data points in Fig. 2 are clearly strongly linearly correlated, but the scatter about a straight line exceeds that due solely to expected experimental error. The scatter cannot be accounted for by system blank

Table 2 Analytical data for Geco pyrites

Sample	Mass (g)	K (p.p.m.)	^{40}Ar* ($\times10^{-7}$ cm^3 STP g^{-1})	^{40}Ar/^{36}Ar	^{39}Ar/^{36}Ar
OGS-10	0.2478	5.6	1.97	393.3±4.5	0.34±0.02
OGS-14	0.2613	8.8	2.56	444.4±2.8	0.54±0.01
OGS-131	0.8568	34.4	7.34	1,219.0±9.0	5.13±0.04
OGS-132	0.8484	16.8	3.72	840.9±15.5	2.88±0.02
OGS-133	0.8933	4.8	2.76	631.1±7.6	0.68±0.01
OGS-134	0.9348	11.9	3.06	521.4±6.3	0.56±0.01

Errors are ±1σ. ^{40}Ar/^{36}Ar and ^{39}Ar/^{36}Ar values have been corrected for a system blank of 1×10^{-8} cm^3 STP. The system blank has atmospheric argon composition.

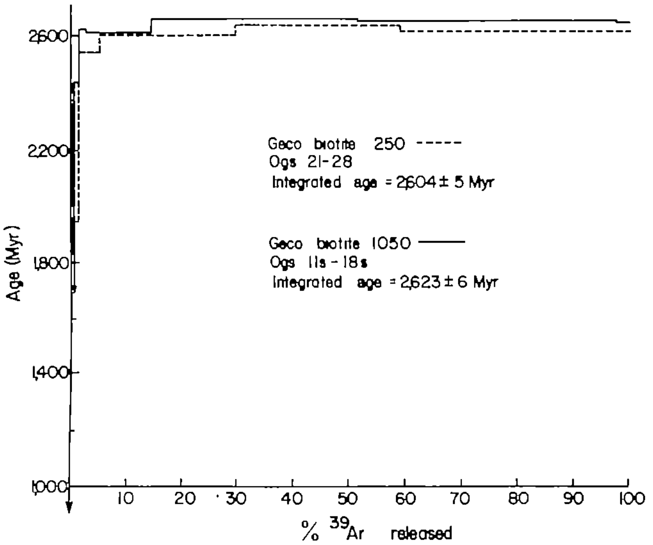

Fig. 1 Step heating data for Geco biotites. The age errors are listed in Table 1.

variation as the blank correction is no more than 5% of the plotted ratios. Thus enormous blank variations would have to be invoked for point OGS-134 (see Table 2).

When a least squares best line[9] is fitted to all the data, the slope corresponds to an age of 2,490±200(1σ) Myr, with an initial ^{40}Ar/^{36}Ar ratio of 369±28(1σ). When the most obviously discrepant point is omitted from the fit, the age and intercept estimates are scarcely changed, but the error estimates are significantly reduced. Thus the age becomes 2,500± 120 Myr, and the initial ^{40}Ar/^{36}Ar ratio is 359±17. The errors quoted in all cases correspond to the observed scatter of the points about the line.

The age indicated by the pyrites is thus indistinguishable, within errors, from that found for the micas, raising the distinct possibility of dating pyrite-bearing ore bodies directly with the ^{40}Ar/^{39}Ar technique despite the extremely low potassium levels. The reason for the scatter of the data in Fig. 2 is not yet clear. However, it is probably a reflection of a lack of homogeneity in the ^{40}Ar/^{36}Ar ratio among the pyrites at the onset of argon retention following the Kenoran orogeny.

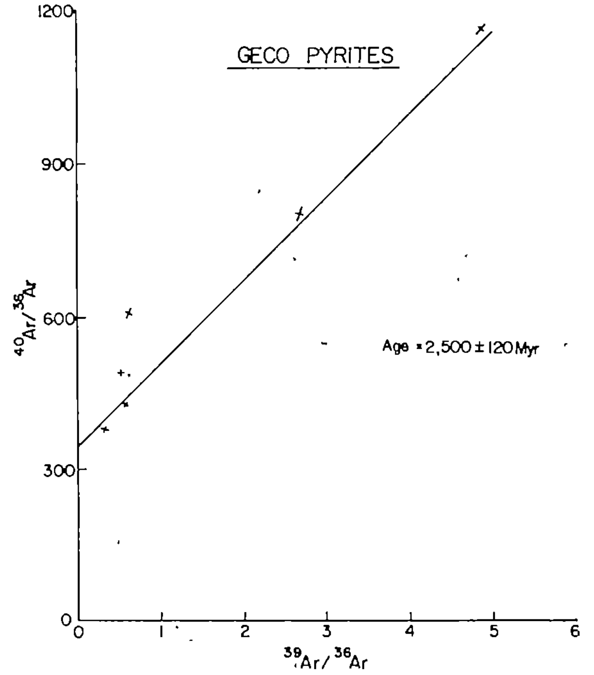

Fig. 2 Isotope correlation plot for Geco pyrites. The least squares best slope through all data points corresponds to an age of 2,490± 200 (1σ) Myr. When the most discrepant point is omited, the best slope corresponds to an age of 2,500±120 Myr. The error bars shown are the principal axes of the error ellipse about each point. The orientation is dependent on the correlation of the ^{40}Ar/^{36}Ar and ^{39}Ar/^{36}Ar errors. All error estimates are 1σ.

At this stage, it is not possible to say where the potassium and argon are located in the samples. All the pyrites were carefully hand-picked and examined to exclude external silicate contamination and the extremely low potassium concentrations found (Table 2) are testimony to the efficiency of this. However, there may have been minute potassium-bearing silicate inclusions completely encased within the pyrite. Some potassium and argon could be present in fluid inclusions, although the chlorine/potassium ratios (0.5–1) estimated from the ^{38}Ar/^{39}Ar ratios were not those characteristic of fluid inclusions ($\simeq$45) (ref. 10).

This investigation was funded with grants from the Ontario Geological Survey and the National Science and Engineering Research Council of Canada.

The photosynthetic membranes in a variety of organisms are involved in the conversion of energy from sunlight into chemically useful forms[1–3]. *Rhodopseudomonas viridis* is a purple non-sulphur photosynthetic bacterium offering unique advantages for the study of photosynthetic membranes. Its internal photosynthetic membranes form large flat sheets which, as first described by Giesbrecht and Drews[4], contain subunits organized into a regular repeating pattern. The membranes are ideally suited to the use of Fourier image analysis techniques, and have been studied in two dimensions[5,6]. We have now determined the three-dimensional structure of photosynthetic membranes of *R. viridis* by electron microscopy. A large central structure protrudes from both surfaces of the membrane, and is surrounded by six smaller centres of mass. Comparison of these data with studies on the polypeptide composition of the membrane suggests a membrane in which a photosynthetic reaction centre is surrounded by light-harvesting bacteriochlorophyll protein complexes.

Membranes were isolated from pressure-disrupted cells as described elsewhere[7]. The membranes were stained with 2% aqueous uranyl acetate on carbon films and examined at tilt angles in an electron microscope ranging from 0° to 61° (Fig. 1). Densitometry and computer processing were carried out on selected micrographs to produce Fourier terms for computing the structure. Fourteen micrographs were used for the analysis, each of which provided as many as 22 individual measurements of amplitude and phase. Many of the micrographs showed regular detail in Fourier transforms extending to four orders (the lattice constant measured from these transforms and from electron diffraction patterns is 100 Å, corresponding to a centre-to-centre distance for membrane subunits of 115 Å),

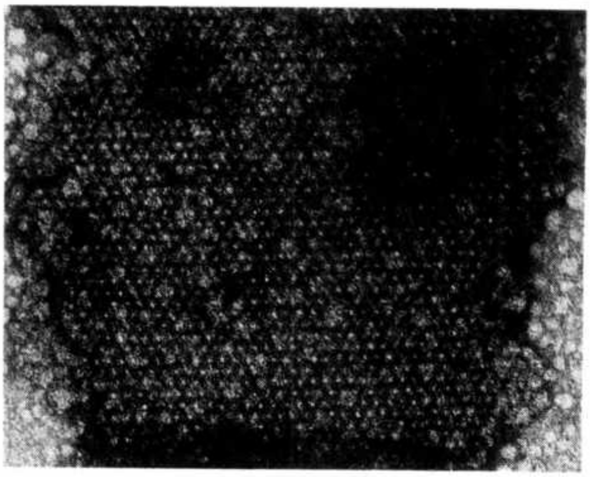

Fig. 1 Isolated photosynthetic membrane from *R. viridis*. The individual subunits can be seen arranged in a hexagonal lattice. The preparation was stained with 2% uranyl acetate. ×147,000.

indicating a resolution of 25 Å, but the final analysis was carried out to three orders for a resolution of 33 Å. Individual micrographs showed projected structure and Fourier terms consistent with the crystallographic space group P6, and the three-dimensional analysis was taken with P6 symmetry, at this level of resolution, applied to the data (see Fig. 2). The average phase residual determined from combining the individual images was 22 degrees, and all Fourier terms were considered in computing phase residuals.

To achieve a proper scaling of amplitude terms in the direction perpendicular to the plane of the membrane, 'edge-on' views of the membrane were also gathered. We used these images in a way similar to that described by Unwin and Zampighi[8] to calculate the 0, 0 lattice line through the origin of the three-dimensional Fourier transform.

The map calculated by these procedures highlights the stain-excluding structures of the membrane, and is subject to the usual difficulties and distortions associated with negative staining. An appropriate contour value was selected and used to produce an outer surface for the structure of each subunit in the membrane. The complete three-dimensional structure of such a subunit is shown in Fig. 3*a*.

A large central structure protrudes from each surface of the membrane, and a ring of smaller centres of mass surrounds it. The approximate width of the entire subunit is 100 Å, and the central region is approximately 70 Å thick. The central protrusion dominates the reconstructed image of the membrane; this domination can be appreciated from individual contour sections as well as from the surface map. Figure 3*b* shows a section through the subunit at the centre of the membrane, with the large central mass region clearly defined. The six 'satellite' regions are also visible, however, showing that the mass of the subunit is not completely restricted to one main region. The model agrees closely with images obtained from other techniques, including deep-etching and rotary shadowing (Fig. 4).

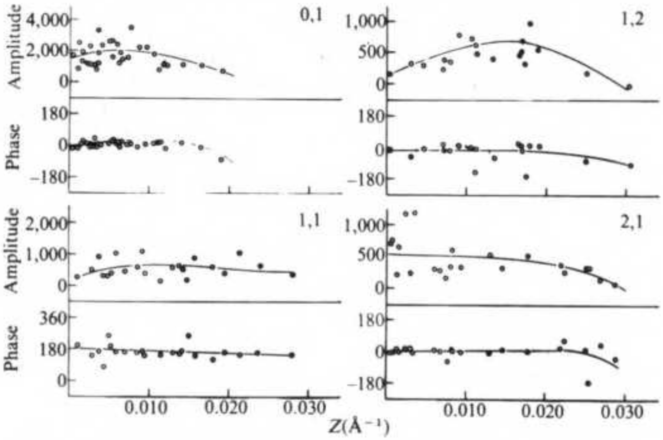

Fig. 2 Phase and amplitude plots of four major lattice lines used for the three-dimensional reconstruction. Values were sampled from these curves for the three-dimensional reconstruction.

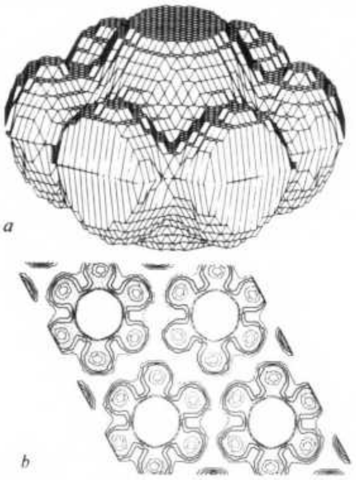

Fig. 3 *a*, Three-dimensional model of an individual membrane subunit. The surface was generated by applying a contour value to the reconstruction data and generating a surface envelope to fit the contour. A large central structure is seen which protrudes from each surface of the membrane, and six smaller lobes surround the protrusion. *b*, Four unit cells, arranged as they exist in the membrane, sectioned along a central plane parallel to the membrane sheet. Only the density of the central region can be seen (and not the projected density of the whole structure). In each subunit, the central region is surrounded by the six 'satellite' regions of mass density. Each central region is completely separated from its neighbour by a ring of such satellites.

Several workers have prepared reaction centres from *R. viridis* membranes[9,10]. X-ray and neutron diffraction studies[11,12] of similar reaction centres, from *Rhodopseudomonas sphaeroides*, in artificial lipid membranes, suggested an asymmetric mass distribution perpendicular to the membrane plane. The *R. viridis* membrane does not display such strong asymmetry, but note that we have used intact membranes rather than isolated reaction centres.

The *R. viridis* photosynthetic membrane contains light-harvesting components as well as the reaction centre apparatus[7,13,14]. A recent study in this laboratory revealed seven

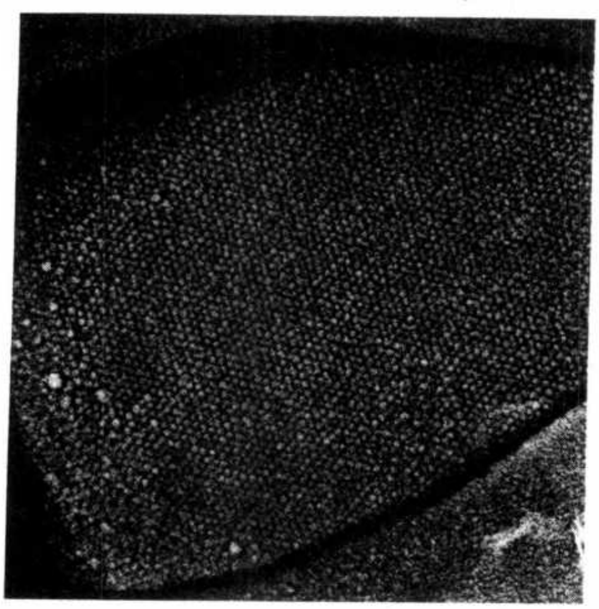

Fig. 4 Outer surface of the *R. viridis* photosynthetic membrane, exposed by deep-etching and rotary shadowing in a freeze-etching device. The lattice is clearly visible and individual subunits are well separated. ×100,000.

polypeptides associated with the intact membrane[7]. Two of the polypeptides (with apparent molecular weights of 11,000 and 16,000) bind bacteriochlorophyll and function in light-harvesting. Of the remaining five, three are associated with the reaction centre itself and two may have a role in electron transport[7]. Interestingly, an analysis of the apparent relative amounts of the seven polypeptides showed that the light-collecting components were present in 6–10 times higher concentration then the other five[7]. It thus seems reasonable to suggest that the 'satellites' of mass around the central structure are related to the two light-collecting components, and that the other five polypeptides (of molecular weights 24,000–44,000) are located in the central structure.

Can the membrane subunits visualized in this study accommodate the seven polypeptides associated with the membrane? We have estimated the volume of each membrane subunit at ~550,000 Å^3 (the volume of a disk 120 Å in diameter and 50 Å thick). Using a value of 1.3 Å^3 per dalton (derived from bacteriorhodopsin[15]), we might expect such a volume to accommodate approximately 423,000 daltons. Using the molar ratios for the seven membrane polypeptides reported by Jacob and Miller[7], we arrive at a value of 535,000 daltons per reaction complex. Although the molecular weight determination is slightly higher than the available volume, the negative staining used to prepare the samples for electron microscopy may have compressed the sample during the drying process, and could easily account for the slight difference. I therefore suggest that each subunit in the membrane contains a complete set (but only one) of reaction centre, electron transport and light-collecting components.

The programs used for data transformation and image recombination were kindly provided by Drs Linda Amos and Richard Henderson. A number of students and co-workers, including Jules Jacob and Yvonne Alvarez, helped with this project. Special assistance with data processing was provided by David Laidlaw, Tanya Falbel and David Salesin. I especially thank Drs Timothy Baker and David deRosier for the use of electron microscopy and densitometry equipment and for advice at several stages of this project. This work was supported by NIH grant GM-28799.

Growth effects of SO_2 and/or NO_2 on woody plants and grasses during spring and summer

Mary E. Whitmore & Peter H. Freer-Smith

Department of Biological Sciences, University of Lancaster,
Lancaster LA1 4YQ, UK

The two most widespread air pollutants in Britain are SO_2 and NO_2 (refs 1, 2). These not only contribute to acidity in rain[3], which may seriously affect plant growth, but also cause substantial effects by their direct action as gaseous pollutants. Research into the effects of the gaseous pollutants on grasses has shown that the combination of SO_2 and NO_2 may be particularly toxic to plant growth[4,5]. Further research in this laboratory showed that *Phleum pratense* L. was more sensitive to SO_2 when growth was slow and it was suggested that exposures during winter may be particularly phytotoxic[6]. Here we present the results of experiments in which serious effects on plant growth were detected even during the summer months. Autumn-sown smooth stalked meadow grass (*Poa pratensis* L.) exposed to SO_2 or SO_2 plus NO_2 showed marked growth reductions during the winter and spring, and although the plants recovered during the summer, flowering was inhibited. Moreover, four broad-leaved tree species showed substantial decreases in growth when exposed to SO_2 plus NO_2 between March and August.

Experiments were done in four large hemispherical glasshouses situated outdoors, in which environmental conditions were close to ambient[7]. Pollutants were added to three of the glasshouses between 09.00 h on Monday and 17.00 h on Friday to give concentrations of 0.1 p.p.m. NO_2, 0.1 p.p.m. SO_2 and 0.1 p.p.m. $NO_2 + 0.1$ p.p.m. SO_2; weekly mean concentrations were 0.062 p.p.m. (Annual means of 0.06 p.p.m. SO_2 and 0.06 p.p.m. NO_2 may be experienced in several urban areas in Britain[8–10] where grasses and trees are grown for amenity purposes.) The fourth glasshouse (control) received partially filtered air without added pollutants.

The amenity grass *Poa pratensis* L. cv. Monopoly was exposed to SO_2 and/or NO_2 for 11 months, during which growth was monitored. Seeds were sown in each treatment on 2 October 1980 and after emergence 15 days later, 110 seedlings were potted into individual 7.5 cm pots containing John Innes no. 2 compost and placed at random within the relevant glasshouse. Samples of 10 plants per treatment were removed for harvesting at intervals until 7 September 1981. Plants were repotted into 10 cm pots in May, after which no further root weight measurements were made. The increases in control plant weight up to mid-May and in shoot weight at this and subsequent harvests are shown as natural logarithms in Fig. 1*a*; per cent reductions for each pollution treatment are illustrated in Fig. 1*b*. Between November and February, SO_2 and NO_2 appeared to interact causing greater than additive effects on plant weight; large reductions were evident in the combined gas treatment, while SO_2 alone caused only small reductions, and NO_2 alone promoted growth ($P < 0.05$). After this time, however, the interaction was lost and effects became approximately additive because small reductions developed in the presence of NO_2. During late spring and summer the polluted plants gradually recovered, until by September, shoot weight in NO_2 was similar to that in controls and that in SO_2 and $SO_2 + NO_2$ exceeded the controls by ~17% ($P < 0.05$). Culm development before flowering was first observed in mid-May and was followed by inflorescence

Table 1 Mean increases in total dry weight (g) of 14 seedlings and 14 cuttings of *Betula pendula* grown in clean air and in air containing 0.05 p.p.m. $SO_2 + 0.05$ p.p.m. NO_2

	Seedlings	Cuttings
Control		
Mean dry weight ± s.e.	4.30 ± 0.376	14.56 ± 0.553
c.v. (%)	32.7	14.2
$SO_2 + NO_2$		
Mean dry weight ± s.e.	3.11 ± 0.367	9.14 ± 0.373
c.v. (%)	44.2	15.3
Decrease in growth of polluted plants (%)	27.7	37.2
LSD between treatment and control means (%), $P = 0.05$	25.1	9.4

The percentage decrease in growth and the least significant differences (LSD) between the polluted and control means for the seedlings and cuttings are also shown.

development towards the end of the month; Fig. 1c shows mean numbers of culms per plant. SO_2, whether supplied alone or together with NO_2, not only delayed stem elongation but also reduced the total number of flower heads to less than half that on controls. The inhibition of flowering may have contributed to the recovery of shoot weight in these treatments by allowing vegetative growth to continue at faster rates than in the controls.

As little is known of the influence of SO_2 and NO_2 mixtures on tree growth, six species were selected for comparison. By using cuttings of only one genotype the variability between replicates can be reduced, and as only a few trees of each species could be accommodated in the fumigation chambers, this meant that small treatment effects would not be masked by plant variability. Therefore, second-year cuttings of *Malus domestica* Borkh. (apple MM 106), *Betula pendula* Roth. (silver birch), *Betula pubescens* Ehrh. (common birch), *Populus nigra* L. (black poplar), and *Alnus incana* L. (grey alder), and seedlings of *Tilia cordata* Mill. (small-leaved lime) were exposed to SO_2 and/or NO_2 from before bud break (23 March) and harvested after 150 days on 19 August 1981. Plants were grown in individual 19 cm Fyba pots containing J.I. no. 2, and were randomly positioned in each of the four glasshouses. The range of responses of the different species to SO_2 and/or NO_2 can be seen in Fig. 2, where the mean dry weights of the fumigated plants are expressed as percentages of the control means. In those species which showed reduced growth in response to pollutants, the combined treatment was the most toxic. There were interactive effects of SO_2 and NO_2 in *T. cordata*, *B. pendula*, *P. nigra* and *B. pubescens*, resulting in greater than additive responses. Those plants which were significantly affected in terms of dry weight also showed significant decreases in stem height and diameter. In some cases visible leaf blemishes were observed on the older leaves of polluted plants, and towards the end of the exposure period accelerated leaf senescence and abscission of the leaves occurred. The early loss of leaves from deciduous trees exposed to small concentrations of SO_2 is well known[11], and in the experiment reported here was found to be greater when NO_2 accompanied SO_2.

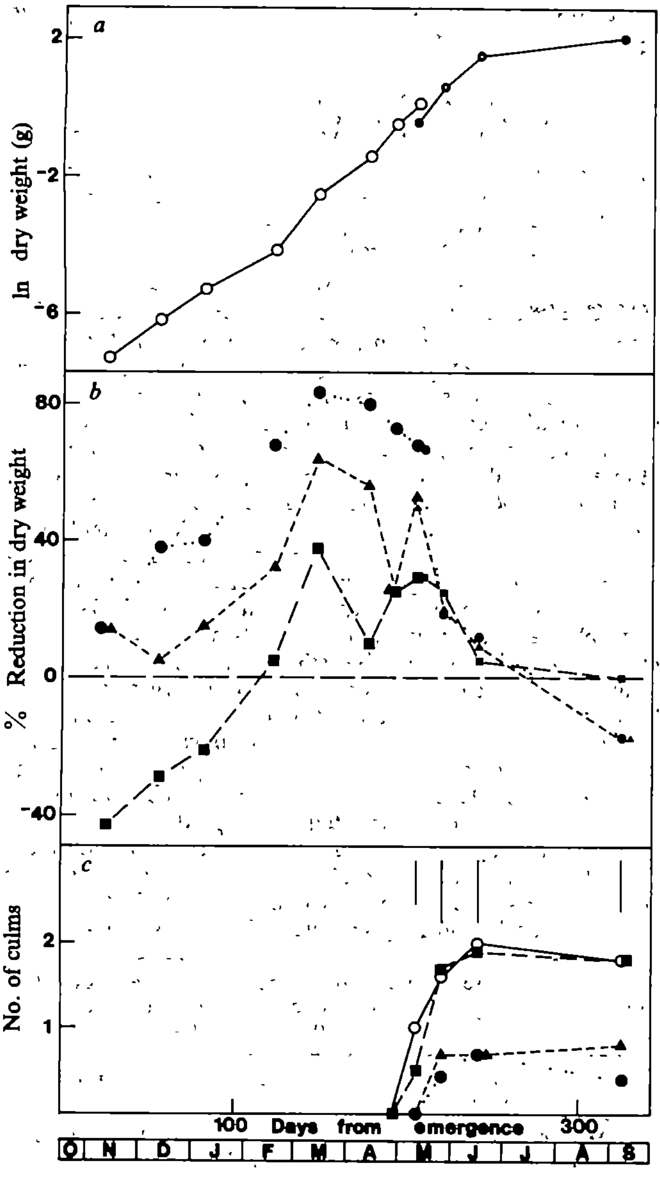

Fig. 1 *a*, Growth of *Poa pratensis* L. in partially filtered air. Plant weights are shown up to May (large symbols) and shoot weights at this and subsequent dates (small symbols). *b*, Percentage reductions in dry weight compared with controls after exposure of plants to weekly mean concentrations of 0.062 p.p.m. NO_2 (—■—), 0.062 p.p.m. SO_2 (– – ▲– –) or 0.062 p.p.m. SO_2 + 0.062 p.p.m. NO_2 (···●···). Large symbols represent effects on plant weight and small symbols effects on shoot weight. *c*, Development of culms: control (—○—), in NO_2 (—■—), and in SO_2 (– – ▲– –) or SO_2 + NO_2 (···●···). Bars represent LSD, $P = 0.05$.

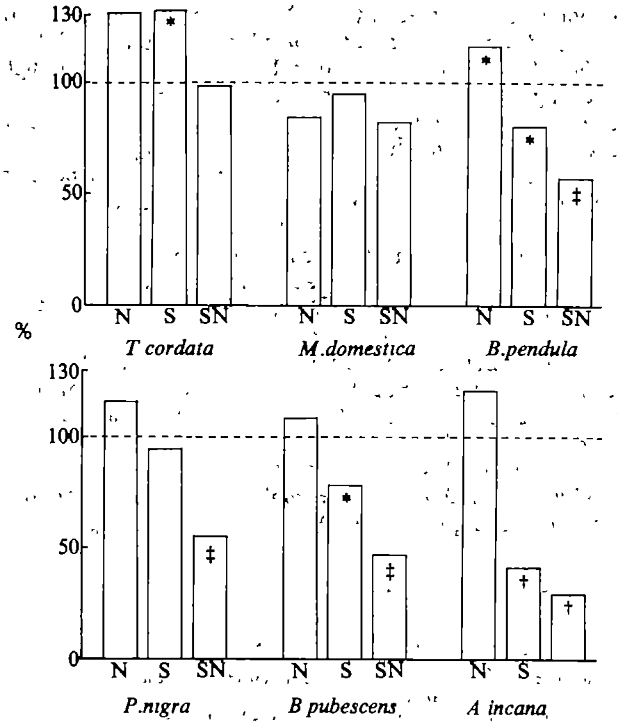

Fig. 2 The mean dry weights of woody plants ($n = 5$–8) exposed to weekly mean concentrations of 0.062 p.p.m. SO_2 (S), NO_2 (N), or $SO_2 + NO_2$ (SN) expressed as the percentage of the mean dry weights of controls grown in clean air. Treatment means that were significantly different from control means are marked: $^*P < 0.05$, $^†P < 0.01$, $^‡P < 0.001$.

To compare the effects of a $SO_2 + NO_2$ mixture on seedlings with effects on cuttings (of one genotype), a further experiment was conducted. Seeds of *B. pendula* collected in autumn 1979 were sown the following summer and cuttings from one seedling were bulked up by micropropagation; 14 seedlings and 14 cuttings were grown in two fumigation chambers from 27 May to 14 August 1981. The chambers were kept outside and were rapidly ventilated with charcoal-filtered air. Pollutants were added to one chamber to give an exposure concentration of 0.05 p.p.m. SO_2 + 0.05 p.p.m. NO_2. Table 1 shows the mean increases in dry weight of the seedlings and cuttings over the 80-day exposure period. The cuttings grew more quickly than the seedlings, but both groups of plants showed decreases in growth in air containing SO_2 and NO_2. The coefficient of variation (%) of each group is also shown and illustrates the greater variability in the growth of the seedlings. Clearly, a smaller treatment response could have been detected with the clonal plant material than with seedlings.

These data show that growth of deciduous species may be severely decreased by exposure to SO_2 and NO_2 mixtures during the growing season. Sensitivity clearly differed between species and the order of relative sensitivity coincided well with assessments made in the field by examining chronic injury at sites near to pollution sources[12]. Exposure to the individual gases caused stimulation of growth in *T. cordata*, *B. pendula* and in the grass *P. pratensis* at some harvests, which suggests that the pollutants provided additional sources of nutrients. Such responses have been reported previously for NO_2 and for SO_2 but are usually associated with conditions in which nutrient supply is limited[13,14].

The changing response to pollutants of the grass studied here illustrates some of the difficulties of predicting effects in the field and of interpreting results from an individual harvest. However, recovery of polluted plants during late spring and summer may not be observed in the field if plants are in competition with less sensitive species. An inhibition of flowering when plants are grown in SO_2-containing air may be of possible benefit in turf cultivation, but could have serious implications for commercial seed production.

We thank the NERC for financial support, Professors T. A. Mansfield and F. T. Last for supervision, and Mrs Wendy Tabner for technical assistance.

Falcon visual sensitivity to grating contrast

Joy Hirsch

Department of Ophthalmology and Visual Science,
Yale University School of Medicine, New Haven,
Connecticut 06510, USA

The eye of a small falcon, the kestrel, is about half the size of the human eye and, if similar in all other respects, its visual acuity would also be expected to be about half that of the human. Here we report that the cut-off frequency (a measure of visual acuity) is twice the expected value and is the same for kestrel and human eyes. This remarkable visual performance is explained by anatomical features of the bird eye and the spherical pit of the deep fovea acting as the diverging element of a telephoto lens to magnify the image[1,2]. In the low-spatial frequency range, however, falcon contrast sensitivity is much less than that of humans for stationary patterns.

Experiments were carried out with a 2-year-old male American kestrel, *Falco sparvarius*, called Argus, hatched in the wild and acquired at about 1 month old. Stimuli were sinusoidal modulations of a homogeneous luminance field, that is, vertical spatial frequency gratings; electronically generated on the screen of a cathode ray tube (Tektronix 606; P31 phosphor). Mean luminance of the field was $\sim$40 cd m^{-2} (calibrated by Tektronix photometer, J16), and was unchanged by modulation. Grating contrast (depth of modulation) was defined as $(L_p - L_t)/2\bar{L}$ where L_p and L_t represent the luminance levels at the peak (maximum) and trough (minimum) of a spatial cycle, and $\bar{L}$ is the average luminance across the screen. Contrast was expressed on a logarithmic scale where contrast in decibels, dB, is equal to $20 \log_{10}$ (contrast). Two conditions were used: (1) stationary gratings with abrupt onset and offset and (2) phase changing gratings that abruptly reversed the sign of modulation every 2 s (0.25 Hz phase reversal). The screen subtended approximately 3 degrees of visual angle on the falcon eye at a distance of 200 cm. A thin vertical line (5 mm wide) bisected the screen into right and left fields. During a trial one side of the bipartite field contained the grating and the other side remained homogeneous at the same average luminance. Stimulus generation and control of the experimental procedure were completely computer-controlled (Digital Equipment Corporation; PDP-11/03).

The experimental apparatus consisted of three perches and a food dispenser. The computer was signalled when the kestrel landed on any one of the perches. The perch from which the stimulus was viewed, P_o, signalled that the kestrel was in the observing position, and initiated presentation of the stimulus. Two response perches, P_r and P_l, corresponding to either the right or left bipartite fields, respectively, were located 5 cm in front of and slightly below the stimulus screen, and signalled a response when pressed. The food tray was located directly above the screen and dispensed a small piece of beef heart when signalled by the computer.

The task for the kestrel was to initiate a trial by landing on P_o, decide if the grating was on the right or left side of the field, and fly to either P_r or P_l to indicate his choice. Argus appeared to scrutinize the stimulus field monocularly by turning his head first with one side towards the stimulus field and then the other before making his response flight. This suggests that the nasal (deep) fovea was used for the judgements required in this experiment. (The nasal fovea contains the highest density of photoreceptors and is used for distant viewing[1].) As soon as Argus left P_o the modulation was automatically removed from the screen to ensure that the response decision had been made at P_o. A food reward immediately followed each correct response. An incorrect response was followed by an auditory signal and the mean luminance was reduced to 0 for 50 s during which a new trial could not occur. Following the 'dark time' the screen returned to the mean luminance level as a ready signal for the next trial. Argus was allowed 100 s of viewing time on P_o before a trial was aborted and a new stimulus presented. A trial was also stopped if Argus left P_o and failed to arrive at either P_r or P_l within 3 s.

A two-alternative forced choice method of constant stimuli was used. The stimuli for each session consisted of one spatial frequency presented at four contrast levels each separated by 5 dB. The side of the screen receiving the modulation was randomly chosen, and the order of presentation of each of the stimuli was also randomized. The spatial and temporal stimulus conditions were selected in irregular order across sessions. Each session consisted of 200 trials, and all trials were included in the analysis. As the experimental procedure was automated, much of each session proceeded in the absence of an experimenter. Usually a session lasted 4–5 h. All sessions started in the early evening.

The probability of a correct response was plotted against stimulus contrast and the psychometric function was fit by eye. The contrast level associated with 75% performance was interpolated from the psychometric function to determine contrast

0028-0836/82/440057—02$01 00

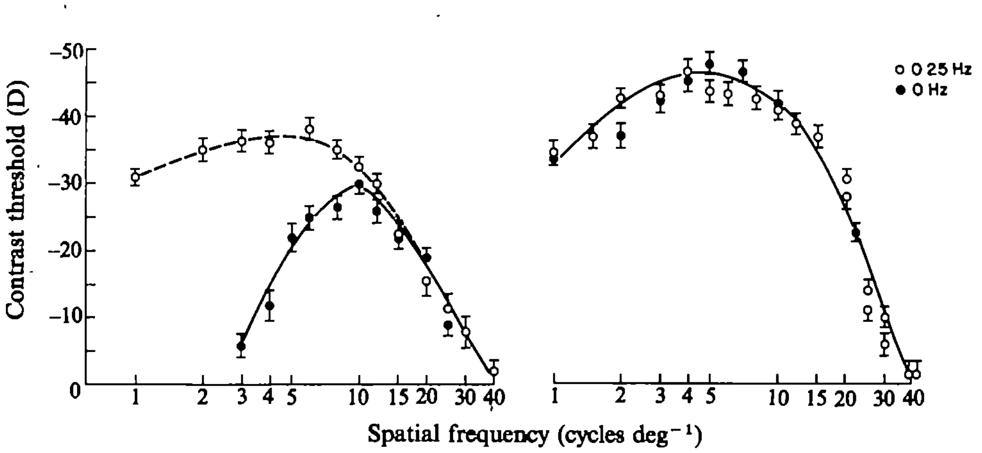

Fig. 1 Contrast threshold (dB) plotted against spatial frequency (cycles deg^{-1}) for falcon (*a*) and human (*b*) observers. Closed symbols represent thresholds for stationary gratings (0 Hz), and open symbols represent thresholds for gratings that abruptly reversed phase every 2 s (0.25 Hz). Data from three human observers (L.K., B.M. and J.H.) are combined on the human function. Error bars represent 1 s.d. of threshold estimates repeated for determination of reliability on about one-third of the data points.

threshold. A threshold was obtained only when the per cent of correct responses extended from 50% to ~90% or more. Many contrast thresholds were replicated at 4- and 6-month intervals to confirm stability of the measurements. A catch trial condition was periodically used where no pattern was presented on either side of the screen. Performance did not significantly differ from 50% in such conditions.

Contrast thresholds were similarly determined for three human observers (L.K., B.M. and J.H.) in the same experimental set-up as was used for Argus. Response keys were substituted for perches, and a synthesized voice unit (Votrax, VS-K) was substituted for the beef heart dispenser. The voice unit provided verbal feedback following each trial; otherwise, the software and data analysis for both experiments were identical. Viewing was binocular for the human observers.

Contrast at threshold was plotted against spatial frequency for both stimulus conditions and is shown in Fig. 1 for falcon and human observers. The data are presented so that the ascending direction of the ordinate represents decreasing contrast and, therefore, increasing sensitivity. The sensitivity of the falcon to stationary gratings was dramatically depressed below 10 cycles deg^{-1} relative to the phase changing gratings, suggesting that falcon vision may be highly dependent on temporal cues for discrimination of spatial frequency gratings below 10 cycles deg^{-1}. A similar low frequency fall-off has recently been reported for the contrast sensitivity function of a large eagle, *Aquila audax*[3]. Human contrast sensitivity functions were similar for both conditions. Absolute levels of peak contrast sensitivity (phase changing gratings) were approximately 0.5 log units lower for the kestrel than for the human. Increased photoreceptor noise, and/or reduced photon capture (possibly due, in part, to the small photoreceptors of the falcon eye) may account for the lower peak sensitivity.

Cut-off frequency for both human and falcon functions was ~40 cycles deg^{-1}. The human spatial cut-off frequency of 40 cycles deg^{-1} observed in this experiment is expected for the luminance level used here[4]. The results for the kestrel are inconsistent with a previous report that kestrel acuity is ~2.6 times higher than that of humans[5]. However, the similar cut-off frequencies for both human and falcon reported here can be explained in terms of the known geometry of the falcon eye and retina.

The falconiform eye is distinguished from other vertebrate eyes by a two-foveal retina[1,6,7], closely-packed foveal photoreceptors[1,2] and superior optics[8]. In general, cut-off frequency of an eye can be estimated from focal length, photoreceptor spacing and pupil diameter[9,10]. Pupil diameter, measured periodically during the experiment by placing a rule about 1 cm away from the eye while Argus was on the observer perch, was ~2.5–3.0 mm, and thus sufficient to pass the spatial frequencies used in this experiment[2]. In falconiform eyes, focal length, F, is ~0.65 of the axial length, L, and can be estimated from head width, W, where $W = 2L$[1,11]. Head measurements made with calipers indicate that $W = 28$ mm for Argus. Thus $F = 9.1$ mm, which is about half the human focal length[10], and therefore limits acuity by a factor of half relative to that of humans. However, centre-to-centre spacing of falconiform foveal photoreceptors, d_{cc}, is 2 μm (refs 1, 2), which is two-thirds of the human value and provides a 1.5 factor acuity advantage for the falconiform. Based on focal length and centre-to-centre spacing of photoreceptors, the predicted cut-off frequency for the falcon would be three-quarters of the observed human cut-off frequency or 30 cycles deg^{-1} against an observed cut-off frequency of 40 cycles deg^{-1}. The boost in falconiform spatial frequency cut-off can be accounted for by an image magnification factor m, as given in the equation[2]

$$\nu = \frac{F}{d_{cc}\sqrt{3} \times 57.3} \times \mathrm{m}$$

where ν is the spatial cut-off frequency in cycles deg^{-1}, and F and d_{cc} are as defined above. If m, the foveal magnification factor, is set equal to 1 for humans then the equation gives a magnification factor of 1.33 for the falcon. Magnification factors due to the spherical pit of the deep fovea have been estimated to be ~1.10–1.25 for the eye of a jumping spider (Salticidae)[12] and 1.45 for a human-size falconiform eye[1]. The magnification factor of 1.33 reported here is consistent with previous estimates and thus may explain the extraordinarily high visual acuity of the falcon given both the advantage of small photoreceptors and the limitation of small eye size.

Gigaseal patch clamp recordings from outer segments of intact retinal rods

P. B. Detwiler, J. D. Conner & R. D. Bodoia

Washington 98195, USA

The hyperpolarizing light response of vertebrate photoreceptors depends on cation-selective ionic channels in the cell membrane, which open in darkness and close in light. Little is known about these channels even though they are crucial elements in the transduction of light into a change in receptor potential. Here we report our attempts to study the light-sensitive channel using a patch pipette technique for recording ionic currents from a small area of outer segment membrane. The electrode was sealed against the membrane with a sealing resistance higher than a gigaohm, permitting good resolution of membrane currents[1,2]. Working at low external calcium concentrations this allowed us to observe in response to light small outward currents (the difference currents observed when the light-sensitive channel closes, thus switching-off an inward dark current), which reversed polarity with membrane depolarization. We were unable to recognize discrete current steps that might represent single channel openings and closings modulated by light. However, the light-induced outward current was accompanied by a decrease in membrane current noise. Analysis showed that the elementary event in 0.1 mM external calcium is ~12 fA. If it is assumed that the elementary event is due to the closure of a single light-sensitive channel and that the potentiating effect of low external calcium on the photocurrent is due solely to an increase in single-channel current, one can calculate that in normal calcium the value of the elementary event is 2 fA, corresponding to a single channel conductance of 50 fS. A conductance of this size is consistent with ion permeation via either a mobile carrier or a pore.

Experiments were performed on the dark-adapted retina of the nocturnal lizard, *Gekko gekko*, which was chosen after unsuccessful attempts to obtain stable patch recordings from other types of photoreceptors. The recording method is shown in Fig. 1*a*. A piece of retina from approximately one-fifth of the eye was isolated and placed in a perfusion chamber with the photoreceptor outer segments oriented parallel to the stage of an inverted microscope. Under visual observation through an IR image converter, the recording pipette was introduced into the chamber from the side and pressed against either the tip or, less frequently, the distal side of the outer segment of single intact rods. For ~60% of the time, brief suction applied to the pipette caused its resistance to increase suddenly from ~4 MΩ to 1–50 GΩ, as has been shown with other tissues[1,2]. Seal resistances in the gigaohm range provide an order of magnitude improvement in current resolution over the recordings obtained using the rod 'sucking' technique[3,4], and allow us to apply voltage steps to the patch without penetrating the cell with microelectrodes.

Over the course of these experiments, gigaseal recordings were obtained from 202 rods, and 49 of these responded to light with an outward change in membrane current. The reason for the low percentage of responding cells is not known. The membrane at the tip of the outer segment, which is shed during receptor renewal, might be abnormally fragile or not always functional. It is also possible that the low yield of responding cells is due either to damage sustained in preparing the isolated retina or to breakage of the outer segment membrane when suction was applied in attempting to form a gigaseal. The incidence of membrane breakage was highest in low Ca^{2+} solutions, which set a practical limit to the amount by which the external calcium concentration could be reduced.

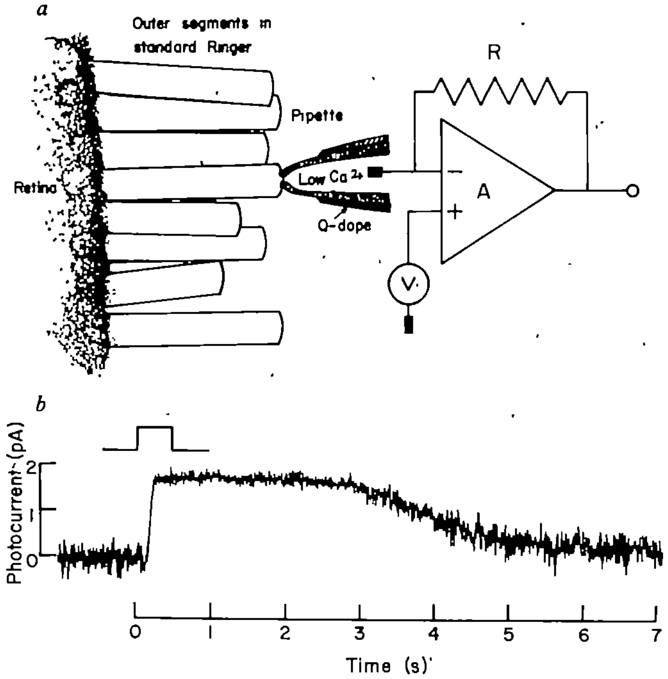

Fig. 1 *a*, Recording method. The isolated retina was anchored in a chamber through which flowed a continuous stream of oxygenated and chilled (~18 °C) Ringer's solution. A fire-polished glass pipette insulated with polystyrene Q-dope (GC Electronics) and filled with low calcium Ringer's solution, was pressed against the tip of a suitable rod outer segment Gentle suction was briefly applied to the inside of the pipette until the seal resistance abruptly increased to >1 GΩ. Ag/AgCl pellet electrodes were used in the pipette and bath. Current flowing across the patch of membrane at the pipette tip was measured with a virtual ground circuit using a 10 GΩ feedback resistor (R). The potential inside the pipette was controlled by a variable voltage source (V). The output of the amplifier (A) was low-pass filtered at 100 Hz or 160 Hz (8 pole), amplified further and recorded on an FM tape recorder. For all experiments, the Ringer's solution contained (mM): NaCl, 159; KCl, 3.3; $CaCl_2$, 1.0; $MgSO_4$, 1.0; dextrose, 10; HEPES, 2.8 (neutralized with NaOH to *p*H 7.8). The pipette filling solution was the same except $CaCl_2$ was 0.1 mM. *b*, Light response of a patch of rod outer segment. The trace shows the recording of membrane current (outward current positive) before and after a 500-ms flash of white light (photocell trace on top); bandwidth d.c. to 100 Hz. Stimulus intensity was 6.25×10^{-10} erg μm^{-2} $flash^{-1}$. Seal resistance 1 GΩ.

Figure 1*b* shows the response of a gekko rod to a moderately bright flash of white light. The outward photocurrent rose rapidly to a peak amplitude which persisted for a few seconds and then declined slowly. The size of the photocurrent produced by saturating light intensities varied from cell to cell over about a tenfold range, with a mean value of 1.6 pA. For the cells having the largest photocurrents, it was possible to see that a protrusion of outer segment membrane had been drawn into the tip of the patch pipette. Since recordings of this type differed from the others only in the size of their light response, we attributed the variations in photocurrent amplitudes to differences in the area of membrane in the patch pipette.

To establish that the observed photocurrents were due to changes in the conductance of the membrane under the recording pipette, we examined the influence of the patch potential on the light response. The potential across the membrane patch was changed by applying the appropriate voltage to the external surface of the membrane patch via the pipette. The inside of the pipette was made negative for depolarization and positive for hyperpolarization. The outward photocurrent observed at resting potential increased in amplitude with hyperpolarization,

0028–0836/82/440059—03$01 00

decreased with depolarization, and appeared as an inward current at potentials displaced by more than approximately +40 mV from the resting potential. Detailed analysis of these experiments is complicated by the fact that the intracellular potential changes during the light response, as the whole outer segment was illuminated. Nonetheless, the results provide evidence that the current response is due to a light-induced conductance change of the membrane patch with a reversal potential of about 0 mV.

The current recorded from a patch of outer segment membrane fluctuated in darkness in an apparently random manner. The peak-to-peak noise in the quietest recordings was 0.1–0.2 pA and contained no recognizable discrete current events that could be considered the opening or closing of single light-sensitive channels. In all cells, steady illumination reduced the current fluctuations. For example, in the experiment of Fig. 2, the current fluctuated over a range of 0.5 pA (peak-in-peak) in darkness with a mean variance of 1.93×10^{-26} A². Steady illumination with a moderate light then produced a maintained outward photocurrent of 0.67 pA, and the mean current variance was reduced to 0.98×10^{-26} A². When the light was turned off, the outward photocurrent declined and the noise recovered slowly over the following 60 s to a final mean value of 1.69×10^{-26} A². The change in variance caused by steady light was calculated by subtracting the grand average of the variances during light from the grand average of the variances measured during the two dark periods. Based on eight cells for which it was possible to obtain sufficiently long and stable recordings during the dark–light–dark sequence, the average value of the reduction of noise by steady light was 1.9×10^{-26} pA². The approximate magnitude of the elementary events underlying the light-suppressed noise was estimated by dividing the change in current variance by the change in mean current[5]. This calculated unit event size did not depend on the intensity of steady illumination, nor did it correlate with the magnitude of the saturating light response produced by the cell. In the eight cells referred to above, the amplitude of the estimated unit event ranged from 4 to 21 fA, with a mean value of 12 fA.

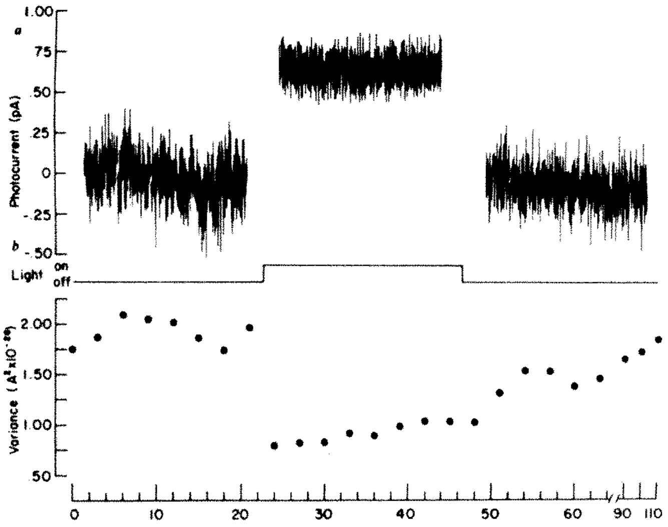

Fig. 2. *a*, Recordings from an outer segment patch in darkness and during steady illumination. The traces shown are representative 2-s long samples of the high gain current record before, during and after steady illumination. The steady outward photocurrent produced by illumination is indicated by the vertical displacement of the trace obtained in light. The output of the light monitor is shown on the middle trace and applies to both parts *a* and *b*. *b*, Graph of the current variance versus time. The continuous current trace was divided into successive 2-s long segments. A laboratory computer (DEC LSI 11/23) was used to digitize signals to form 1,024 points at 2-ms intervals, and to calculate the variance within each 2-s long segment[14]. The dark values in the text are the averages of a larger number of values than are shown in the graph. The return of noise following illumination was initially sluggish, approximating the initial dark level 45–60 s after the return to darkness (note break in the time axis). Bandwidth d.c. to 160 Hz; stimulus intensity 326 photons μm^{-2} s^{-1} at 520 nm; seal resistance 3 GΩ.

Our results do not allow us to decide what the unit event represents. It could be the change in membrane current due to the closure of a single light-sensitive channel, or the spontaneous release of a packet of transmitter substance resulting in the fairly synchronous closure of a number of channels. If we assume that the unit event we have measured is due to the closure of a single light-sensitive channel, we can make several inferences about the properties of the channel. The recordings described here were obtained in an external medium containing 1/10th of the normal calcium concentration. Previous measurements in rods have shown that lowering the external calcium concentration increases the light-sensitive current[6–9]. Decreasing the external calcium concentration from 1 to 0.1 mM is associated with an approximate fivefold increase in photocurrent[9]. The mechanism of this effect is unknown; however, it could be that low calcium concentrations increase the single channel conductance and/or the number of functioning light-sensitive channels. Preliminary experiments have not allowed us to choose between these alternatives. It is interesting, however, that if external calcium influenced the photocurrent solely through an action on the conductance of light-sensitive channels, then the estimated unitary event in normal calcium would drop to 2 fA. This value agrees remarkably well with the shot event size calculated on more theoretical grounds for toad rods[10]. With a unit event of this size, a 1 pA single-photon response would require the simultaneous closure of ~500 channels. Furthermore, if the maximum photocurrent produced by the outer segment is between 20 and 30 pA (ref. 4) than the total number of light-sensitive channels would range over 10,000–15,000 per outer segment, giving a channel density of 10–15 μm^{-2}.

The experiments that measured the reversal potential of the light response indicate that the driving force on the light-sensitive channel is ~40 mV. A unit event of 2 fA would then correspond to a single channel conductance of 50 fS. This is ~140 times smaller than the conductance of a single electrically excitable sodium channel[11]. The flux through a channel this size would be 1.25×10^4 sodium ions per second, which is of the same order as that for a shuttle-type mobile carrier like valinomycin[12,13]. It has been reported[9] that in 0 Ca-EGTA the photocurrent increases approximately 20-fold. If we retain the assumption that external calcium influences solely the single-channel current then the flux through the channel could be as large as 2.5×10^5 ions per s. This rate of ion permeation is intermediate between what could be accomplished by a carrier and what is clearly a pore. The argument for a mobile carrier would be strengthened if the unit event we have measured involved a number of permeation sites. Our results are thus compatible with either a carrier or a pore being responsible for ion movement through light-sensitive channels in the rod outer segment.

Cholecystokinin activation of single-channel currents is mediated by internal messenger in pancreatic acinar cells

Y. Maruyama & O. H. Petersen*

The Physiological Laboratory, University of Liverpool, PO Box 147, Brownlow Hill, Liverpool L69 3BX, UK

Cholecystokinin (CCK) is one of several active peptides that have been isolated from both the gut[1] and the brain[2]. CCK evokes membrane depolarization and conductance increase in both pancreatic acinar cells[3,4] and pyramidal neurones of hippocampus[5]. In the acinar cells, activation of cholinergic muscarinic and two different peptidergic receptor sites (for CCK and bombesin) result in the same type of conductance increase[6]. The application of intracellular Ca mimics the action of the agonists[7] and Ca has been proposed as an intracellular mediator for the membrane conductance increase[8]. A cation channel activated by internal Ca has been directly demonstrated in single-channel current recording experiments on isolated patches of plasma membrane from the basolateral surface of pancreatic acini[9]. We now demonstrate that CCK and acetylcholine (ACh) can activate these inward current channels indirectly. Single-channel currents were observed in electrically isolated membrane patches *in situ* when micropipette application of CCK or ACh was made outside the patch area. Single-channel currents from the same membrane patches were subsequently recorded after they had been excised (inside-out) and identical values for the single-channel conductance were obtained (~35 pS). No effect of CCK was obtained in the presence of the specific receptor antagonist dibutyryl cyclic GMP[10–12] although in all such cases single-channel currents were subsequently recorded from the excised patch (Ca-activated). These results demonstrate directly that CCK and ACh control ion channel opening via an intracellular messenger (Ca).

We used collagenase-isolated mouse pancreatic acini prepared as described previously[13,14]. Single-channel current recordings from the basolateral plasma membrane were made *in situ* or in excised membrane patches (Fig. 1) using the techniques described by Neher and collaborators[15,16]. The acini were stimulated by local micropipette application of ACh or cholecystokinin-octapeptide (CCK$_8$; Cambridge Research Biochemicals, CCK$_{26-33}$ octapeptide amide, sulphated) in the presence or absence of the specific CCK antagonist, dibutyryl cyclic GMP (Sigma)[10–12].

The experiments always began by recording from patches *in situ* as shown in Fig. 1*a*. Good seals between pipette and plasma membrane (>20 GΩ) were obtained in patches from 25 batches of mouse pancreatic acini. In the absence of agonist the patches were, in most experiments, completely silent (Fig. 2*a*). Spontaneous unitary currents were only observed in two patches; these were not studied further. Patches were sometimes monitored for long periods (up to 20 min) without stimulation. The initially silent patches did not subsequently develop spontaneous activity. In experiments designed to investigate the effect of CCK, this agonist was delivered by diffusion of the hormone from the tip of a micropipette brought close to the acinar unit from which high resolution current recording was made (Fig. 1*a*). Because the CCK-containing pipette was moved gradually until the tip was at a distance of about 20 μm from the site of the electrically isolated patch (an inverted microscope with ×500 magnification was used), it was impossible to obtain very accurate values for the latency of activation of the single-channel currents evoked (Fig. 2*b–e*). The activity normally appeared 20–40 s after the pipette had reached its final position. In six experiments on six different membrane patches, CCK stimulation resulted in the appearance of unitary current steps of the type shown in Fig. 2*b–g*. The recordings were very stable and currents at many potential levels could be monitored in each individual experiment. The linear single-channel current–voltage (*I–V*) relationship (see Fig. 3*a*) gave a 35-pS single-channel conductance. After a suitable amount of data had been recorded at various potential levels, the patch pipette was withdrawn from the acinus and the tip passed through the bath solution–air interface once or twice to form an inside-out membrane patch[16] (Fig. 1*b*). High resolution current recording was continued and unitary current steps were always observed in this condition (Fig. 2*h*). Again, currents were recorded over a wide range of membrane potentials. The current–voltage relationships shown in Fig. 3*a* make clear that the single-channel conductance obtained in the excised patches is virtually the same as *in situ*. In the isolated patches, reversal of current polarity always occurred at zero pipette potential (symmetrical solutions) where *in situ*, reversal occurred at a pipette potential of −25 mV (Fig. 3*a*). A separate series of four experiments on excised patches in which normal ionic gradients were present (physiological saline with 'extracellular' composition in pipette and 'intracellular' fluid in bath) was also carried out. In these experiments, in which the transmembrane ionic gradients correspond to the *in situ* recording situation, the usual type of unitary current activity was seen (Fig. 2*i*, *j*) and *I–V* relationships were obtained (Fig. 3*b*). The single-channel conductance was the same as in the other experiments, with current

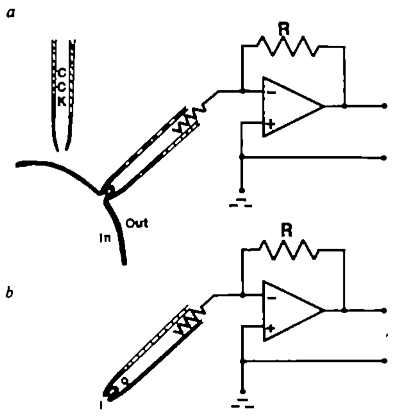

Fig. 1 Schematic outline of experimental system *a*, Recording from *in situ* membrane patch. Fabrication of patch pipettes and recording system as previously described by Neher and collaborators[15,16]. In these experiments the recording pipette was always filled with the bath solution, which had the following composition (mM): 140 NaCl, 4.7 KCl, 2.5 CaCl$_2$, 1 13 MgCl$_2$, 10 glucose and 10 HEPES. The solution was titrated to *p*H 7.3 by NaOH No agonist was present in the pipette solution. The pipette labelled CCK contained the octapeptide in a concentration of 5 μM dissolved in 0 9% NaCl acidified to a *p*H of 4 0 by HCl No currents were applied to this pipette It has previously been shown that glass micropipettes filled with the CCK analogue caerulein will cause substantial depolarization of mouse pancreatic acinar cells (microelectrode experiments) when the tip is placed close to the outside of an acinus[24] Similar experiences have been gained with CCK pipettes In this work the spontaneous diffusion of CCK from the tip of a micropipette was therefore used as the means of stimulation. In experiments with ACh stimulation the pipette was filled with 2 M ACh–Cl A braking current of 20 nA was used. During stimulation an ejecting current of 500–1,000 nA was applied. *b*, After the *in situ* recording the patch-clamp pipette was withdrawn from the acinus under investigation and the tip passed through the bath fluid–air interface to obtain an excised inside-out membranne patch[16] In these experiments single-channel recordings were made in symmetrical saline solutions. In other experiments the bath fluid was changed to one having an intracellular composition (mM) of 145 KCl, 10 NaCl, 1 13 MgCl$_2$, 10 glucose, 10 HEPES and 10 μM CaCl$_2$ with *p*H of 7.3 This enabled single-channel currents from excised patches to be recorded in conditions with normal transmembrane ionic gradients

Pipette potential +50 mV. *i*, *j* show currents recorded from another excised (inside-out) membrane patch with intracellular solution (high K, low Na) in the bath and the normal extracellular solution in the pipette. Pipette potential +60 mV in *i* and −60 mV in *j*. Dashed lines represent the current level when all channels are closed. Downward deflections represent the current from extracellular to intracellular side of membrane

reversal occurring at a pipette potential of −5 mV (Fig. 3*b*). The difference between this reversal potential and the reversal potential obtained in the *in situ* recording situation (−25 mV) indicates the existence of a 20 mV inside negativity in the intact acini during CCK stimulation. This corresponds reasonably well to values obtained with microelectrodes[3].

The effect of CCK application was also investigated in a series of experiments in which a specific CCK antagonist (dibutyryl cyclic GMP)[10–12] was present in the bath solution. In none of the six experiments carried out did CCK stimulation evoke any unitary current steps (Fig. 4*a*, *b*) although the usual type of currents were readily seen after excision of the patch and exposure of the physiological inside of the membrane to the high Ca concentration of the bath fluid (Fig. 4*c*, *d*). In one experiment, CCK stimulation for 4 min in the presence of antagonist did not produce any unitary current steps, but when the patch was subsequently excised the usual activity appeared. The effective CCK concentration surrounding the acinar membrane is, of course, not known in this type of experiment. The result, showing that 1.5 mM dibutyryl cyclic GMP can completely abolish the effect of CCK, indicates, however, that the CCK concentration is unlikely to have been higher than 10^{-9} M (ref. 10).

The effect of ACh stimulation was investigated in experiments with ionophoretic agonist application. In these experiments the ACh pipette could be brought close to the acinus without stimulating the cells by applying a braking (retaining) current. Effects of ejecting ACh from the pipette by ionophoresis were observed after latencies of about 10–40 s. The evoked unitary currents were indistinguishable from those evoked by CCK and the *I–V* relationships were virtually identical (Fig. 3*c*). Subsequent current recordings from an excised patch gave the usual pattern of unitary current steps with the same single-channel conductance (Fig. 3*c*).

In three experiments on excised inside-out patches (extracellular solution on both sides), removal of Ca from the bath (nominally Ca-free solution with 1 mM EGTA) rapidly abolished unitary activity (within 10–20 s), confirming our previous finding on rat pancreas[9]. In the mouse the effect of Ca removal was rapidly (10–20 s) and virtually completely reversible on Ca readmission (300 μM). In the excised patches the apparent number of channels varied between 2 and 10 with 3 or 4 channels per patch representing a common pattern in these experiments (Fig. 4).

This study of the action of CCK and ACh at the single-channel level provides direct evidence for the hypothesis previously advanced that in several gland cells, hormones and

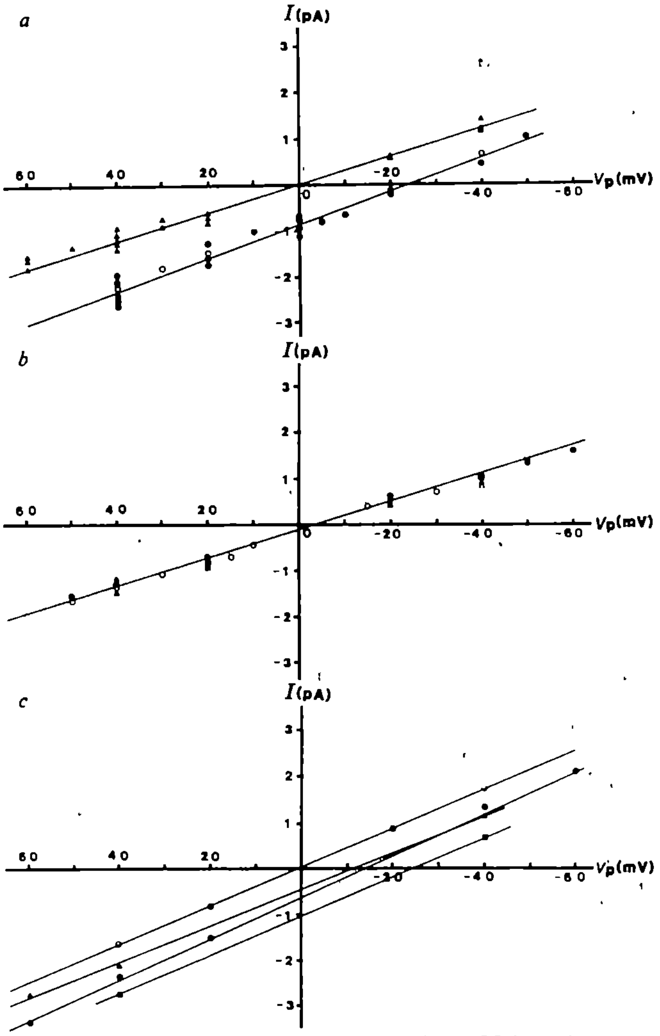

Fig. 3 Single-channel current–voltage relationships. *a*, CCK experiments. Circles represent the data from the six experiments in the *in situ* recording situation. The reversal potential corresponds to a pipette potential of about −25 mV. After excision of the patches (successful in five of the six experiments) the current–voltage relation is as represented by the triangles (symmetrical extracellular solution). The reversal potential corresponds to a pipette potential of 0. The open circles and triangles represent data from the experiment shown in Fig. 2*a–h*. *b*, Data from four excised patches (inside-out) with asymmetrical solutions. Extracellular solution in pipette and intracellular solution in bath. Reversal potential corresponds to a pipette potential of about −5 mV. *c*, ACh experiments. Filled symbols represent three individual experiments where recordings were made *in situ*. Reversal potential corresponds to a pipette potential of about −20 mV. The open circles represent data from the same experiment as the closed circles, but after excision of patch. Symmetrical saline solutions were used and the reversal potential corresponds to a pipette potential of 0.

neurotransmitters control membrane permeability indirectly, via an intracellular messenger[8,17]. CCK-binding studies on pancreatic acini have revealed the existence of about 10,000 receptor sites per cell[12]. If our patches have a membrane area of about 10 μm^2 (ref. 16), we estimate that there are 100–600 channels per cell (assuming 2–10 channels per patch and one acinar cell having 600 μm^2 plasma membrane[18]). The ion transport pathway involved, a Ca-activated inward current channel, has only recently been described in cultured cardiac cells[19], neuroblastoma cells[20] and pancreatic acinar cells[9]. The experiments described here indicate that at least in the pancreatic acinar cells a hormone and a neurotransmitter can control the activation of this channel. Since CCK and ACh have been shown here to activate channels in an area (the patch area) to which these stimulants had no access, the existence of an internal messenger is postulated. Internal Ca can activate the channels and is an obvious candidate.

The mechanism for control of ion transport identified here at the single-channel level, may be the main controlling step for trans-acinar sodium and fluid transport (secretion)[17,21]. In the toad urinary bladder, current noise measurements by Lindemann and collaborators[22,23] indicate that the main hormonal (aldosterone and oxytocin) control of transepithelial Na transport (absorption) is exerted at the Na entry step by determining the number of open channels in the luminal membrane. In the pancreas, we calculate that the channels activated by CCK or ACh can account for an inward current, in the whole of an acinar unit, of up to 50 nA at a membrane potential of −30 mV, assuming an average patch area of 10 μm^2 (ref. 16), an average channel density of three per patch—the channels being open half the time[9], and using known values for the membrane surface of acinar cells and the number of cells in an electrical unit (~500)[21]. This maximal current is more than sufficient to account for the macroscopic currents actually measured in experiments with microelectrodes in which 1 μM ACh was shown to evoke an inward current of about 4 nA, accounting quantitatively for the stimulated acinar Na secretion[21].

The Ca-mediated opening of cation channels in the basolateral acinar plasma membrane evoked by CCK or ACh may represent the major control step for acinar fluid secretion in the pancreas and probably also other exocrine glands, such as the salivary glands and the lacrimal glands, where similar types of stimulant-evoked currents have been studied[17], although not at the single-channel level.

This work was supported by an MRC project grant.

Human T-cell leukaemia virus (HTLV) has been isolated from several cases of cutaneous T-cell lymphoma in the United States[1,2]. Subsequently, adult T-cell leukaemia virus (ATLV) was also isolated from several cases of adult T-cell leukaemia in Japan[3–5]. Since the latter disease has been shown to be correlated ≥90% with the presence of high titred natural antibodies[6–8] to two structural proteins of HTLV [p24 (ref. 9) and p19 (ref. 10)], it was important to compare HTLV and ATLV. We report here that by serology of p24 and p19 and by nucleic acid homology, ATLV appears to be as closely related to the original isolate of HTLV as different isolates of HTLV (from various regions of the world) are related to each other. ATLV is therefore either identical or closely related to HTLV.

HTLV, which has recently been identified outside the United States (refs 8, 11, 12, and M.P. *et al.*, in preparation) can routinely be isolated from HTLV-positive T-cell malignancies now that mature human T cells can be cultured in liquid suspension[13–15] in the presence of T-cell growth factor[16,17]. Integrated proviral sequences have been detected in DNA of the HTLV-positive leukaemic T cells but not in DNA from normal uninfected human tissues[2,8,18,19], establishing HTLV as an acquired retrovirus of man. Moreover, sera from the HTLV-positive patients contain specific, high-titre antibodies to p24[20], the major core protein of HTLV[9] and to other HTLV structural proteins[21]. Sera from adult T-cell leukaemia (ATL) patients (from south-west Japan, where ATL is endemic)[22] also contained high-titre antibodies to HTLV structural proteins[6–8]. Independently, workers in Japan (including I.M.) described ATLV retrovirus particles in a cell line established from a patient with adult T-cell leukaemia (MT-1)[3] and in a cord blood T-cell line (MT-2) established by co-cultivation with T cells from a similar patient[4]. Serum antibodies apparently directed against this virus have also been demonstrated, both in Japanese ATL cases and in some normal people in the endemic regions[3,4]. ATLV has since been shown to possess biochemical properties typical of retroviruses[5] and is present in tumour cell but not normal cell DNA[5].

Characterization of p24[9], p19[10], reverse transcriptase[23] and nucleic acids[2,18] of HTLV shows that it is not closely related to any animal retroviruses other than having some distant similarities of amino acid sequence to p24 of bovine leukaemia virus[24]. The experiments reported here were designed to determine whether, as suspected, ATLV is the same virus as HTLV. Indirect immunofluorescence (IF) using a monoclonal antibody to HTLV p19[10], competitive radioimmunoassays utilizing homogeneously purified HTLV p24[9], and nucleic acid assays with HTLV ^{3}H-cDNA and ATLV ^{32}P-cDNA for viral mRNA and proviral DNA[2,5,18] were used to ascertain the relatedness of ATLV to previously described strains of HTLV.

DNA was prepared from the nuclear fraction of MT-1 cells and assayed for the presence of HTLV-related proviral DNA, using highly labelled ^{3}H-cDNA prepared from melittin-permeabilized[25] HTLV virus and using DNase-digested calf thymus DNA as a random primer for the endogenous reverse transcriptase. DNA from cells producing HTLV (clone B2) hybridized with HTLV cDNA with a $C_0t_{1/2}$ value of ~600 (Fig. 1), commensurate with a copy number of 3–4 per haploid genome and consistent with earlier data[18,19]. DNA from HL-60, a human myeloid leukaemia cell line[26], does not hybridize detectably to HTLV cDNA, also in keeping with earlier results with DNA from many different human and animal cell lines and fresh tissues not producing HTLV[18]. In contrast, DNA from MT-1 hybridizes extensively to HTLV cDNA. At the highest C_0t value tested (38,000), the per cent hybridization had not reached an apparent plateau (Fig. 1*a*), but was already 80% of the maximum value observed with clone B2 DNA. Due to the lengthy incubation period required, we did not test higher C_0t values. The high $C_0t_{1/2}$ of the reaction with MT-1 DNA (~1.7×10^{4}) is indicative of a copy number sufficiently low (one per eight or nine haploid genomes) to suggest that less than every cell in this line is infected. This is in keeping with earlier data on viral protein expression[3]. The high degree of homology to HTLV indicates that the detected provirus is

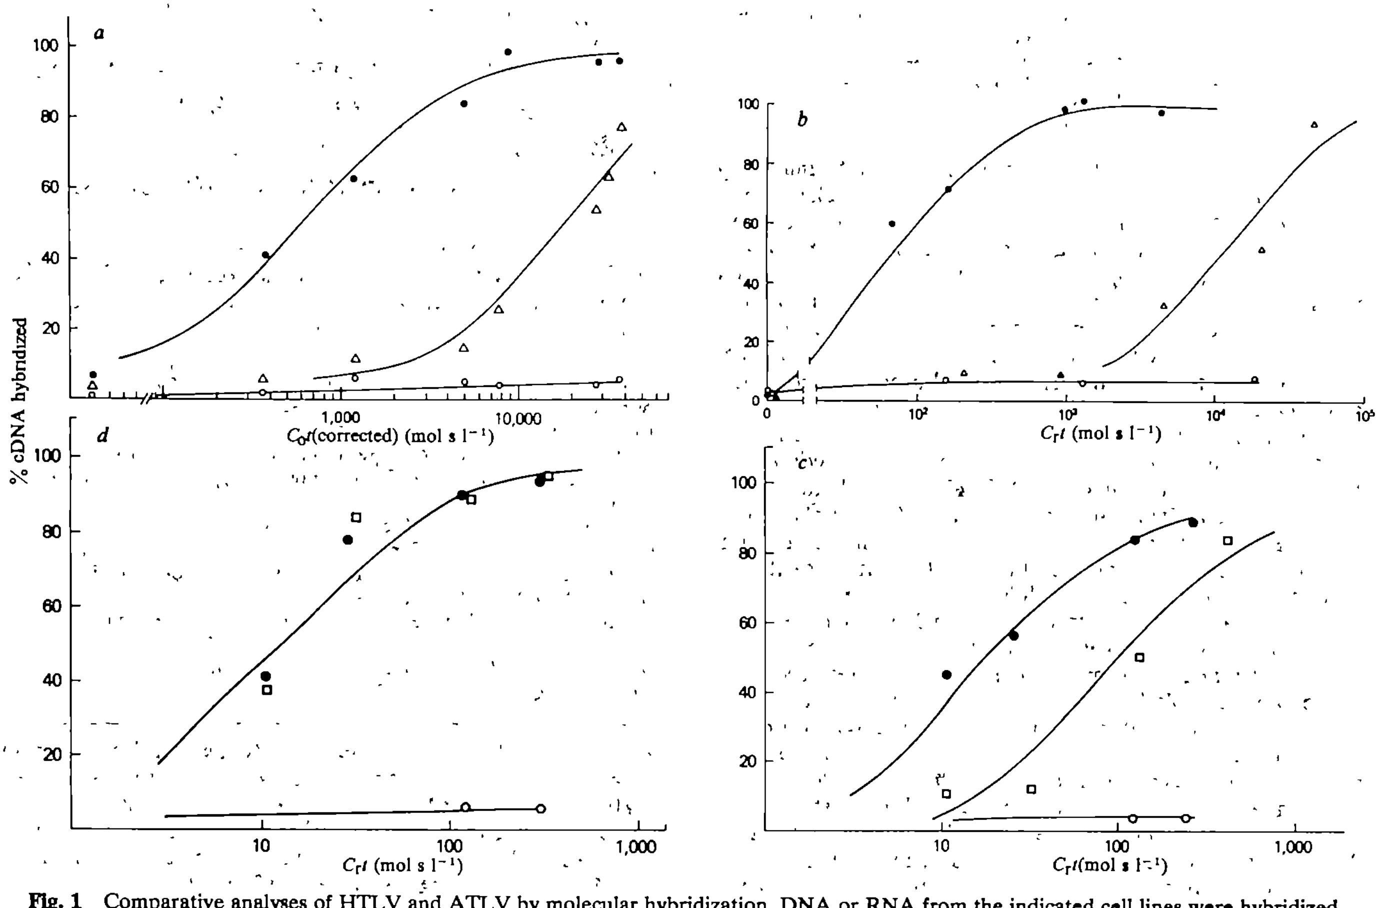

Fig. 1 Comparative analyses of HTLV and ATLV by molecular hybridization. DNA or RNA from the indicated cell lines were hybridized with HTLV ^{3}H-cDNA (*a–c*) or ATLV ^{32}P-cDNA (*d*) to the indicated C_0t (corrected) or C_rt and assayed for hybrid formation by digestion with S$_1$ nuclease as described previously[18]. Each point was determined with 500–1,000 c.p.m. cDNA and was corrected for the zero time point (5–8%) and normalized so that the homologous value = 100% (actual value 45–60%). DNA or RNA were from: clone B2 (●); MT-1 (△), MT-2 (□) and HL-60 (*a*) or CR-B cells (○) (*b–d*). *a*, ^{3}H-HTLV cDNA was hybridized to the indicated DNA (600 µg per point in 25 µl). *b*, ^{3}H-HTLV cDNA was hybridized to the indicated RNA. Clone B2 and CR-B cell RNA were poly(A)-selected and present at 25 µg per 80 µl; MT-1 RNA was unselected and present at 57 µg per 25 µl. *c*, ^{3}H-HTLV cDNA was hybridized to the indicated RNA. MT-2 RNA was not poly(A)-selected and present at 10 µg per 25 µl. *d*, ^{32}P-ATLV cDNA was hybridized to the indicated RNA.

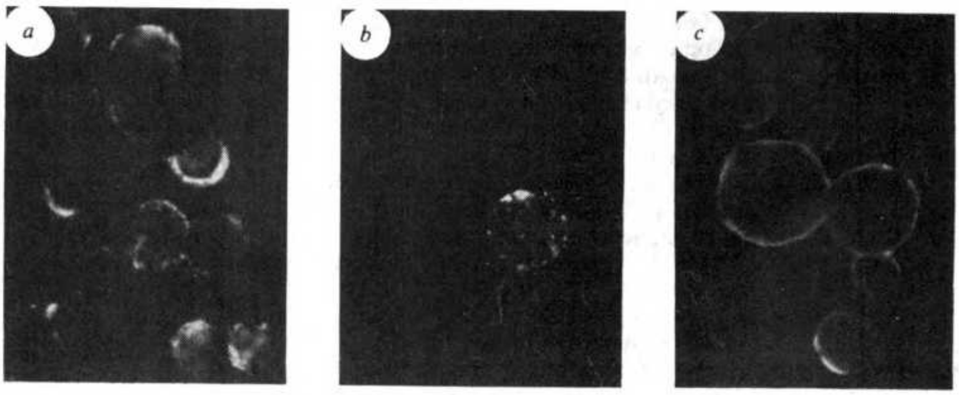

Fig. 2 Indirect immunofluorescence assay using monoclonal anti-HTLV p19. Cells were washed and fixed for 10 min with 50% methanol/50% acetone as described previously[10]. The indirect immunofluorescence assay using mouse ascites fluid containing monoclonal anti-p19 and fluorescein isothiocyanate (FITC)-conjugated F(ab')$_2$ fragment of sheep anti-mouse IgG has also been described elsewhere[10]. *a*, HUT102, clone A9 cells. *b*, MT-1 cells following treatment with 60 μg ml^{-1} IdUrd for 24 h and an additional 24 h in culture in the absence of IdUrd. *c*, MT-2 cells.

identical to HTLV or is a very closely related strain of the HTLV group. Total cytoplasmic RNA was also prepared from MT-1 cells and assayed for the presence of HTLV mRNA. At sufficient C_rt values, similar levels of hybridization are attained with MT-1 RNA and RNA from HTLV-producing cells (Fig. 1*b*), confirming that HTLV is present in MT-1 cells.

In separate experiments, HTLV and ATLV cDNA[5] were hybridized to RNA from a second cell line producing ATLV, and the values obtained were compared with those obtained with RNA from clone B2. As shown in Fig. 1*c*, HTLV cDNA hybridizes to the same extent to both RNAs, indicating that MT-2, like MT-1, contains sequences extensively related to HTLV. Moreover, ATLV cDNA also hybridizes to the same extent to both RNAs (Fig. 1*d*), confirming the close relatedness of ATLV to HTLV in reciprocal hybridization experiments. The difference in the rates of hybridization of HTLV and ATLV cDNA to MT-2 RNA (Fig. 1*c, d*) is noteworthy. HTLV ^{3}H-cDNA is randomly primed and presumably reasonably representative of the RNA genome, while ATLV ^{32}P-cDNA[5] is primarily 'strong stop' cDNA, specific to the 5′ end of the RNA (M.Y., unpublished results). The disparity in the rates of hybridization of the two cDNAs suggests that MT-2 cells express RNA transcripts which consist partly of viral leader sequences and partly of cellular sequences. This interpretation is consistent with the relatively complex pattern observed with Northern blots of MT-2 RNA using ATLV cDNA[5], where several RNA species are evident in addition to the two viral mRNAs observed with MT-1 RNA.

MT-1 cells were assayed for the presence of p19 by indirect immunofluorescence using a highly specific monoclonal antibody[10]. Anti-p19 antibody specifically labelled all six cell lines previously shown to contain HTLV (not shown), as determined by virus isolation, detection of HTLV nucleic acids and detection of antibodies to HTLV in serum from the patient. A battery of HTLV-negative cell lines (a total of 127) which included human normal and neoplastic T and B cells and several human and animal cell lines infected with or producing different animal retroviruses, were always negative. HTLV p19 was detected in a small number (~1%) of MT-1 cells. The number of fluorescent cells increased to ~8% on treatment with iododeoxyuridine (IdUrd). These numbers, although relatively low, are highly reproducible and are consistent with both the low estimated proviral copy number mentioned above and with the results of Hinuma *et al.*[3]. Virtually all the cells in the T-2 culture express HTLV p19. The range of p19-positive cells by this assay in other HTLV-producing cell lines is 5–95%. The highest percentage of anti-p19-labelled cells (besides that with MT-2) was observed with clones B-2 and A-9, derived from the HUT102 cell line (M. Maeda, M.P. and R.G., unpublished). Two additional HTLV-producing cell lines, CTCL-3[1] and CTC-16[27], established independently from the same patient (C.R.) as the HUT102 cell line, contained 20 and 38% positive cells, respectively. The proportions of fluorescent cells in CTCL-2[2] and a newly established HTLV-positive neoplastic human T-cell line, MJ (M.P. *et al.*, in preparation), were 5 and 85%, respectively.

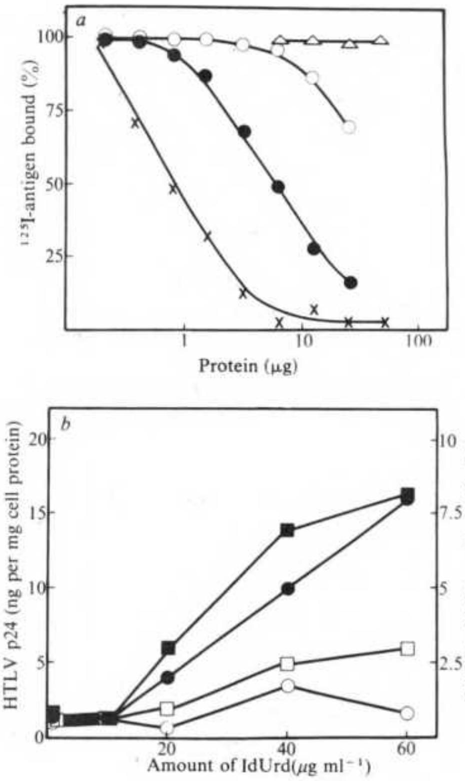

Fig. 3 Competition radioimmunoassay of HTLV p24. *a*, Homologous competition radioimmunoassay of HTLV p24. Competition radioimmunoassays were carried out with ^{125}I-labelled HTLV p24 and a limiting dilution of a rabbit antibody to HTLV. Serial dilutions (100 μl) of the solubilized cells in buffer 1 (20 mM Tris-HCl, *p*H 7.5, 200 mM NaCl, 1 mM EDTA, 0.3% Triton X-100, 0.1 mM phenylmethylsulphonyl fluoride and 2 mg ml^{-1} bovine serum albumin) were incubated with rabbit antibody to HTLV (50 μl containing 1:50 diluted normal rabbit serum) for 1 h at 37 °C. Labelled HTLV p24 (8,000 c.p.m.) in 50 μl of buffer 1 was then added and the mixture was further incubated at 37 °C for 2 h and overnight at 4 °C. A 20-fold excess of goat anti-rabbit IgG was then added and the volume was made up to 1 ml in buffer 1. The samples were further incubated at 37 °C for 1 h, 2 h at 4 °C and then centrifuged at 2,5000 r.p.m. for 5 min in a Beckman centrifuge. The supernatants were aspirated and the radioactivity in the pellet was determined in an LKB ultro-gamma counter. ×—×, Clone B2 cells; ●—●, MT-1 24 h after IdUrd induction; ○—○, uninduced MT-1 cells; △—△, cultured normal human T cells. *b*, IdUrd induction of HTLV p19 and p24 in MT-1 cells. Expression of HTLV p19 and p24 was quantified according to methods described in Figs 2 and 3 legends. Cultured MT-1 cells were exposed to different concentrations of IdUrd for 24 h and the cells were washed free of IdUrd and HTLV p19 and p24 were measured 0 and 48 h later. ○, ●, p24; □, ■, p19. Open symbols, 0 time after the 24 h IdUrd treatment; filled symbols, 48 h after removal of the IdUrd from the culture medium.

These cell lines, like CTCL-3 and CTC-16, were established from the peripheral blood of patients with leukaemia or lymoma involving relatively mature T cells. An example of the immunofluorescence obtained using monoclonal anti-p19 antibody on MT-1 and MT-2 cells and a positive control cell line, clone A9, is shown in Fig. 2.

A specific competition radioimmunoassay has been described for the HTLV core protein, p24[9], which can detect as little as 0.05 ng of p24. This precipitation assay uses ^{125}I-labelled homogeneous HTLV p24 and a hyperimmune rabbit antiserum against detergent-disrupted HTLV. Competition is observed only with proteins from disrupted HTLV or HTLV-producing cells. As shown in Fig. 3*a*, cell extracts from both MT-1 and the HTLV-producing cell line, clone B-2, competed in the HTLV p24 radioimmunoprecipitation assays. The competition with IdUrd-induced MT-1 cells was about 10-fold higher than with untreated MT-1 cells, and the slope and end point of the competition curves with clone B2 and induced MT-1 were the same. The p24 determinants of HTLV and ATLV which are recognized by this antiserum are thus indistinguishable. No competition was observed with extracts from HTLV-negative control cells, which included cultured human normal mature T cells and leukaemic T-cell lines previously shown to be HTLV negative.

The kinetics of induction of expression of p19 and p24 were analysed in parallel after treatment of MT-1 cells with IdUrd for 24 h. As shown in Fig. 3*b*, the induction of both proteins was time-dependent and increased with increasing concentrations of inducer. There was a slight increase in the expression of both p19 and p24 immediately following the 24-h treatment of MT-1 cells with IdUrd. However, a substantial increase in the expression of both proteins was observed 48 h after IdUrd treatment. At the highest IdUrd concentration tested (60 μg ml^{-1}), the p19 expression increased about 8-fold while a 16-fold increase was detected for p24 compared with the untreated control cells. The expression of both these proteins therefore increased simultaneously on IdUrd treatment of MT-1 cells. It is therefore likely that the 'adult T-cell leukaemia-associated antigen' or 'ATLA' in MT cells detected following induction with IdUrd and using natural antibodies in sera of Japanese ATL patients[3], represents one of these previously described HTLV proteins[9,10].

We have previously shown that >90% of tested Japanese patients with ATL also contained antibodies to HTLV p24[6-8]. A subsequent more extensive screen of a large number of sera of Japanese ATL patients has substantiated the earlier finding[28]. In addition, 25% of close relatives of ATL patients and about 10% of individuals in the area endemic for ATL also have antibodies to HTLV p24. In contrast, none of 40 normal random sera from the non-endemic regions of Japan had anti-HTLV p24 antibodies.

We conclude from the data presented here that the antigens reacting with the antibodies in the sera of most Japanese ATL patients are highly cross-reactive with HTLV proteins p19 and p24. Two cell lines from such patients (MT-1 and MT-2), which contain ATLV RNA and proviral DNA[5], also contain viral nucleotide sequences which are virtually indistinguishable from those of HTLV. MT-1 (which produces ATLV[3]) expresses two antigenic determinants indistinguishable from those of HTLV p24 and p19. Virtually all MT-2 cells (which produce ATLV[4]) express HTLV p19. Moreover, three other Japanese ATL cell lines established in our laboratory (M.P. *et al.*, in preparation) and two other similar lines established in Japan (S. Morikawa, personal communication) also express antigenic determinants indistinguishable from those of HTLV p24 and p19. The widespread occurrence of antibodies in the Japanese ATL sera strongly reactive with HTLV p24 further strengthens our conclusion that the retrovirus associated with Japanese ATL is identical or very closely related to previously described strains of HTLV[1,2,18] which have been isolated and characterized from patients in the US with leukaemias and lymphomas involving mature T cells, and establish ATLV within the HTLV group.

We thank M. Jarvis, E. Richardson and E. Shepard for technical assistance. Fixed cells from MT-2 were provided by Dr Y. Hinuma. M.P. was a recipient of the American Cancer Society, Eleanor Roosevelt International Cancer Fellowship awarded by the International Union Against Cancer.

Human T-cell clones recognize chemically synthesized peptides of influenza haemagglutinin

The continual variation in the antigenic structure of the haemagglutinin (HA) molecule is associated with the appearance of new epidemics or pandemics of influenza in immune populations[1]. The detailed analysis of HA structure has provided the molecular basis of this phenomenon[2-4] and while four antibody-binding sites have been suggested[4], the epitopes of HA that are recognized by T cells remain undefined. Using chemically synthesized peptides corresponding to sequences of the HA molecule[5], we have investigated the antigenic determinants recognized by long-term T-lymphocyte lines and clones induced with HA and maintained in T-cell growth factor (TCGF or interleukin-2, IL-2). The data suggest that HA-specific T-cell populations contain the repertoire to respond to all the synthetic peptides analysed. However, when responses are analysed at the clonal level, one peptide located at the carboxy-terminus of the HA1 molecule and discrete from the proposed antibody-binding sites[4] seems to be immunodominant.

Peripheral blood lymphocytes (PBL) from adult volunteers selected for known responses to strain A influenza virus (A/Texas/1/77; H_3N_2) were cultured with HA isolated from this subtype. After 6 days, cultures were either cloned by limiting dilution in the presence of TCGF, irradiated autologous PBL and specific antigen as previously described[6], or maintained as cell lines. The T lymphocyte clones and lines were maintained in continuous culture for 8 weeks and then assayed for responsiveness to specific antigen in the presence of antigen-presenting cells as determined by tritiated thymidine (^{3}H-TdR) incorporation.

Normal PBL responded to the intact virus and to the HA molecule of A/Texas/1/77, as did long-term influenza and HA lines induced with the same viral subtype (Table 1). The antigenic specificity of these lines was confirmed by their failure to respond to the unrelated strain B influenza virus, B/Singapore/222/79. Both normal PBL and T-cell lines in the presence of antigen-presenting cells responded to each of the synthetic peptides (Fig. 1) tested over a dose range of 0.01–10 μg ml^{-1}. Although these peptides were synthesized according to the sequences of influenza strain X-47 (ref. 7), in most cases they were identical to corresponding regions of A/Texas/1/77 (ref. 8). Both viruses are H3N2, and comparison of their sequences reveals only a few amino acid differences. It is evident that peptide 20, which corresponds to the carboxy-terminus of HA1, induced the maximum proliferative response (Table 1). Interestingly, this peptide is distant from the four proposed antibody-binding sites. Although these sites are able to induce proliferation, it appears that they are not the immunodominant region of the HA molecule for T-cell responses. In comparison, studies on immune responses to myoglobin in mice have demonstrated that the five antigenic sites recognized by antibody are also the primary inducers of T-cell proliferation in cell populations[9,10] and long-term cultures[11]. Furthermore, it was reported that peptides representing B-cell non-antigenic parts of the molecule were unable to induce proliferation[10], which may reflect the fact that regions of myoglobin are phylogenetically conserved and are thus immunologically silent. However, our findings demonstrate that the entire HA molecule as defined by the synthetic peptides used in these studies can induce T-cell proliferation with none of the peptides behaving as nonimmunogens, as was observed in myoglobin[10], or actively inducing suppression, as has been reported for lysozyme[12,13]. Analysis of the activity of smaller peptides of HA, however, may allow such regions to be identified.

Table 1 Reaction of normal peripheral blood lymphocytes and influenza A virus- and HA-specific long-term T-cell lines with synthetic peptides of the HA1 molecule

Synthetic peptides of HA-1 molecule	Normal PBL	Lymphocytes Influenza A line	HA line

Normal human peripheral blood lymphocytes (PBL, 2.5×10^5 ml^{-1}) were cultured with either the synthetic peptides of the HA1 molecule, the purified HA molecule (gift of Dr R G Webster), or intact influenza A (A/Texas/1/77) or B (B/Singapore/222/79) strain virus for 6 days in RPMI-1640 (Gibco) supplemented with 10% pooled A$^+$ serum. The concentration of antigen used for the synthetic peptides and HA was 0.01–10 μg ml^{-1}, and 0.05–50 haemagglutinating units (HAU) ml^{-1} for the intact viruses. To induce T-cell lines, PBL were cultured with intact A/Texas/1/77 or the purified HA molecule of A/Texas, and after 6 days the lymphoblasts were enriched on a discontinuous Percoll gradient. These blast cells (10^5 ml^{-1}) were expanded as long-term T-cell lines with filler cells (irradiated (2,500 rad) autologous PBL at 5×10^5 ml^{-1}) and specific antigen in the presence of T-cell growth factor. TCGF was prepared by culturing PBL (1×10^6 ml^{-1}) with 0 1% purified phytohaemagglutinin-P (PHA-P; Difco) in RPMI-1640 supplemented with 1% autologous plasma[17]. After 48 h, supernatants were collected and assayed for their ability to support growth of a TCGF-dependent line as described previously[6]. The lines were maintained with filler cells and antigen every 7 days and TCGF every 3 days Influenza A virus and HA-specific T-cell lines (2.5×10^4 ml^{-1}) were cultured with the panel of antigens in the presence of irradiated autologous PBL ($1\ 25\times10^5$ ml^{-1}) for 72 h, pulsed for 8–16 h with 1.0 μCi of tritiated methylthymidine (^{3}H-TdR, NEN) and collected on to glass fibre filters. Proliferation, as correlated with ^{3}H-TdR incorporation, was measured by liquid scintillation spectroscopy[6]. Results are expressed as mean c p.m ($\pm$s.e.m.) of triplicate cultures. Only the highest proliferative response in the antigen dose–response curve is shown As controls, the responses to medium alone, TCGF and B/Singapore were determined.

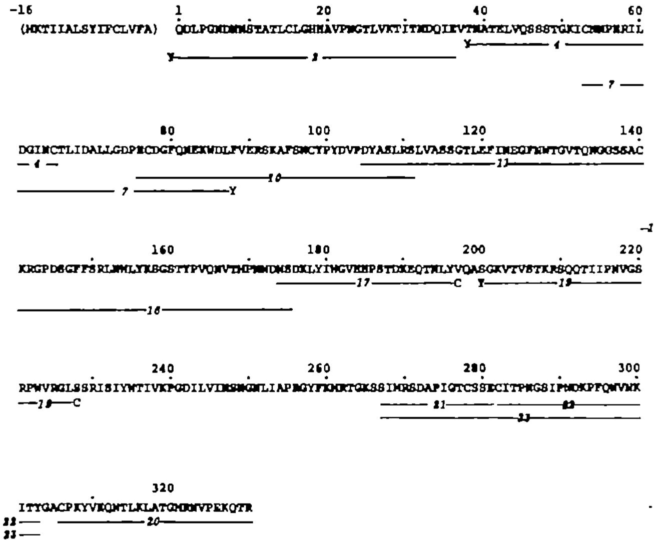

Fig. 1 Amino acid sequence of the HA1 molecule of X-47 as predicted from the nucleotide sequence[7]. The regions of the molecule synthesized are underlined and numbered. C and Y at the end of the peptide indicate, respectively, the addition of a cysteine or tyrosine not present in the primary sequence.

The fine specificity of antigen recognition by HA-specific T cells was investigated at the clonal level using chemically synthesized peptides of HA1 (Table 2). One of the four T-lymphocyte clones (HA1.9) proliferated in response to the HA molecule and the intact influenza A virus, but failed to respond to B/Singapore or to the panel of synthetic peptides. Presumably, this clone recognizes determinants that reside in the sequences not covered by overlapping peptides (Fig. 1). The remaining three clones analysed (HA1.4, HA1.7 and HA2.43) responded only to peptide 20 and not to the predominant antibody-binding sites. Comparable to this observation is a report on the clonal analysis of T-cell recognition of the antigenic determinants of myoglobin, where two clones specific for the fragment 1–55 failed to respond to peptide 15–22, which contains the only antibody-binding site[11].

To define the epitope specificity of T-cell antigen recognition, clones HA1.4, HA1.7 and HA2.43 were cultured with the intact viruses A/Japan/305/57 (H2N2) and A/Texas/1/77 (H3N2). Neither clone HA1.4 nor HA1.7 responded to A/Japan, but both proliferated in response to stimulation with A/Texas (Table 3), suggesting that these two clones recognize a variant region of the carboxy-terminus of HA1. Any one of the amino acid substitutions between A/Japan and A/Texas occurring within the sequence of peptide 20 at residues 312–314, 316, 321 and 326–329 (Fig. 2) would be able to confer the specificity of these clones for A/Texas as opposed to A/Japan, as it has been reported that T-cell activation may

HA-specific human T-lymphocyte clones were isolated as described previously for influenza A virus[6]. Briefly PBL were cultured for 6 days with 0.1 μg ml^{-1} HA. The lymphoblasts enriched on a discontinuous Percoll gradient and resuspended at $33\frac{1}{3}$ cells ml^{-1} in RPMI–1640 supplemented with 10% A^+ serum and 20% TCGF, were plated out at one cell every third well in Terasaki trays with 10^4 irradiated autologous PBL and 0.1 μg ml^{-1} HA. After 7 days, growing clones were transferred to 96-well microtitre trays and then to 24-well trays Then they were expanded in 25-cm^2 tissue culture flasks. At each transfer the T-lymphocyte clones received fresh TCGF and irradiated autologous PBL, together with specific antigen. The clones were maintained with 20% TCGF every 3–4 days and irradiated autologous PBL and HA were added every 7 days. Before use in proliferation assays, the clones were allowed to rest for 6–7 days after the addition of filler cells. HA-specific clones (2.5×10^4 ml^{-1}) were cultured with the synthetic peptides of HA1 molecule (0.01–10 μg ml^{-1}), HA molecule (0.01–10 μg ml^{-1}), A/Texas/1/77 (0.05–50 HAU ml^{-1}) or B/Singapore/222/79 (0.05–50 HAU ml^{-1}) in the presence of irradiated autologous sheep erythrocyte rosette-negative (E^-) cells (2.5×10^4 ml^{-1}) for 72 h, and proliferation measured by ^{3}H-TdR incorporation. E^- cells were fractionated as described previously[6]. Results are expressed as mean c.p.m. (±s.e.m.) of triplicate cultures. Both the lowest and highest proliferative responses for the antigen concentrations used are shown for the synthetic peptides.

Table 3 Specificity of T-cell clones for A/Japan/305/57 (H2N2) and A/Texas/1/77 (H3N2) subtypes of influenza A virus

Fig. 2 Amino acid substitutions between A/Japan/305/57 and A/Texas/1/77 occurring within the sequence of peptide 20. The sequence comparison was derived from Gething *et al.*[2]. The sequence numbering is according to Min Jou *et al.*[7] in order to conform with our peptide designations. The boxed areas indicate substitutions.

be sensitive to a single amino acid substitution[14,15]. In contrast to clones HA1.4 and HA1.7, clone HA2.43 recognized both viral subtypes, which implies that it recognizes an invariant sequence of peptide 20, or less likely that the amino acid substitutions between A/Japan and A/Texas are insufficient to cause modification of the molecule to influence T-cell antigen recognition[14].

The findings reported here do not resolve the issue of the nature of T-cell recognition in terms of a defined amino acid sequence or its dependency on tertiary structure[16]. In an attempt to define the epitope sequence, subunits of peptide 20 were generated with the four carboxy-terminal amino acids and increasing the subunit sequence progressively by four amino acids until the complete peptide was synthesized. Unlike the intact peptide, however, none of the subunits induced proliferation of the clones (data not shown). This result does not distinguish whether the amino terminus of peptide 20 is the precise sequence recognized or whether it dictates the conformation of the native peptide necessary for T-cell recognition. An alternative explanation is that the subunits themselves cannot adopt the same conformation as in the intact peptide, therefore they are no longer recognized by the T cells.

The technical assistance of Ms B. Ketteter is acknowledged. Linkage relationship of a cloned DNA sequence on the short arm of the X chromosome to Duchenne muscular dystrophy

J. M. Murray*†, K. E. Davies*, P. S. Harper†, L. Meredith†, C. R. Mueller‡ & R. Williamson*

* Department of Biochemistry, St Mary's Hospital Medical School, University of London, London W2 1PG, UK
† Department of Medical Genetics, University Hospital of Wales, Cardiff CF4 4XN, UK

Duchenne muscular dystrophy (DMD) is one of the most common and serious human X-linked disorders. It occurs at a frequency of up to 1 in 5,000 newborn males in most populations studied, with about one-third of all cases due to new mutations[1]. The primary biochemical defect remains unknown, and no proven prenatal diagnostic test exists, although raised serum creatine kinase levels act as a somewhat equivocal guide to carrier females[2]. Previous studies have shown no measurable genetic linkage of the *DMD* locus with any X-chromosome marker[3,4]. Therefore, if a cloned sequence of the X chromosome could be used to define the locus, and to provide a closely linked set of markers, it would be of considerable importance in the prediction and prevention of DMD, as well as a step towards identifying the basic biochemical defect causing the disease. We present here evidence of an X-chromosome sequence, defined by its restriction enzyme polymorphism, that is loosely linked to *DMD*, at a distance of approximately 10 centimorgans, as determined by studies on nine informative families. The polymorphism occurs in 29% of women in a control London population and in 22% of carriers for *DMD*. The linkage data support cytogenetic evidence that *DMD* is on the short arm of the X chromosome. The object of this letter is to encourage others to make use of our probe, which seems to be linked to the *DMD* locus.

Restriction fragment length variation results from changes in the primary DNA sequence, such as single base changes introducing or deleting a restriction site, or sequence deletions, additions or translocations affecting the length of DNA between sites. These DNA sequence polymorphisms are inherited in a mendelian fashion and may be used in conventional linkage studies[5–8]. Variations in restriction sites around the human β-globin genes have been estimated to occur once in every 100 base pairs[9]. Polymorphisms are sufficiently frequent in the human genome to assume that one will be found adjacent to any random cloned DNA probe several kilobases (kb) in length. A set of such sequences can be used to construct a linkage map of the entire human genome, or of a particular chromosomal region[6,10–13].

We have previously cloned a collection of sequences from the human X chromosome in λ phage after sorting using a cytofluorimeter; approximately 50,000 clones were obtained, sufficient to ensure that >90% of sequences from the X chromosome are represented in the library[14].

Single-copy sequences were identified in the X-chromosome library using Benton–Davis screening[15] to total labelled human DNA; clones containing repetitive elements present at >100 copies in the genome hybridize and are labelled in the reannealing conditions used[16]. One of the single-copy clones obtained, given the laboratory acronym λRC8, was characterized by hybridization to *Eco*RI-digested human DNA, DNA from various rodent–human hybrid cell lines containing X chromosomes or fragments as the only human genome component, and mouse DNA using Southern blots[17].

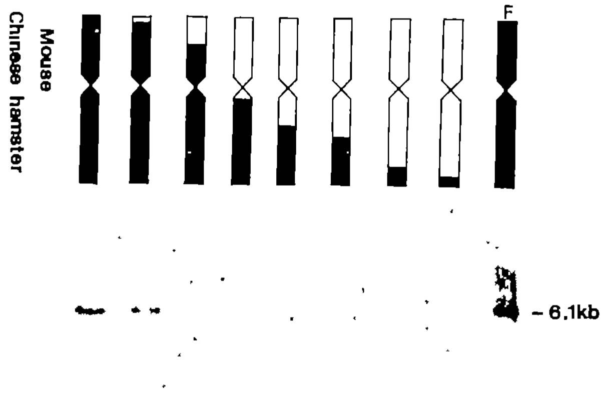

Fig. 1 Localization of λRC8 to the region Xp21–Xp223 using *Eco*RI-digested DNA from a panel of rodent–human cell hybrids. Positioned above each lane is a representation of the human X chromosome, shaded to show the portion which is present in the hybrid cell line from which the DNA was obtained (from left to right): Chinese hamster parental cell line, mouse parental cell line; hybrids containing part or all of the human X chromosome: Xpter–Xqter, Xp223–Xqter, Xp21–Xqter, Xq12–Xqter, Xq21–Xqter, Xq22–Xqter, Xq26–Xqter, Xq28–Xqter, fibroblast cell line (F). These cell lines were characterized cytogenetically and by isozyme markers in the department of Genetics, University of Freiburg. High molecular weight total DNA was extracted, digested and analysed by Southern blotting as previously described[23,24]. Blots were washed in 1×SSC at 65 °C and autoradiographed at −70 °C for 72 h.

This clone contains a 6.1-kb insert of human DNA and hybridizes to a single 6.1-kb band in *Eco*RI-digested human genomic DNA, and DNA from HORL9.X cells (a mouse–human hybrid cell line in which the only human chromosome is the X chromosome), but not to mouse DNA (Fig. 1). It hybridizes to 46XY, 46XX and 48XXXX genomic DNAs with an intensity relative to the number of X chromosomes present (not shown), demonstrating that it is X-chromosome specific. In hybridizations to total human DNA it gives a slight background after moderate stringency washes (1×SSC) which disappears after washing filters at a higher stringency (0.1×SSC) and does not interfere with the analysis reported here.

Somatic cell hybrids were used to locate the DNA sequence cloned in λRC8 to a region of the X chromosome. Hybridization of the clone to DNA samples from various rodent–human cell lines containing portions of the human X chromosome localized λRC8 to the region Xp21–Xp223 (Fig. 1). There was no correlation between hybridization and the spectrum of autosomes present in these cell lines.

Table 1 Linkage data for Duchenne muscular dystrophy, probe λRC8, Xg blood group and colour blindness (CB)

Results are expressed as lod scores (log of the odds) for different values of recombination fraction (θ) The number of kindreds informative for each comparison is indicated (n).

0028-0836/82/440069—03$01 00

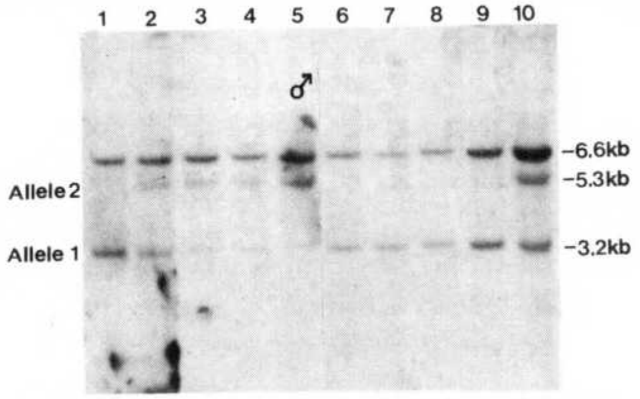

Fig. 2 Variants identified by λRC8 in *Taq*I-digested total DNA from obligatory carriers of DMD. Sample 5 is from the affected son of obligatory carrier 2. Heterozygotes have bands at 5.3 and 3.2 kb; homozygotes have either the 5.3- or 3.2-kb band. Blood samples (10 ml) were taken from Duchenne patients, carriers and normal controls and total DNA prepared[24]. *Taq*I-digested DNA (10 μg) was analysed by Southern blotting[17,23]. After washing to moderate stringency (1×SSC), filters were autoradiographed using Fuji X-ray film and intensifying screen for 72 h at −70 °C.

λRC8 was used to identify polymorphisms by screening panels of normal female DNAs digested with different restriction enzymes. It was found to give a variable pattern of bands with *Taq*I-digested total human DNA, hybridizing to the following fragments: an invariant band of 6.6 kb and a second fragment of either 5.3 or 3.2 kb (Fig. 2). The cloned sequence did not identify polymorphisms with 15 human DNAs digested with *Msp*I, *Xba*I, *Bam*HI or *Sst*I.

Females showing hybridization to both 5.3- and 3.2-kb bands are heterozygous for the restriction fragment length polymorphism: they have one X chromosome which gives a 6.6-kb plus a 3.2-kb fragment (pattern 1), and a homologous X chromosome where the *Taq*I site is altered and the probe hybridizes to give fragments of 6.6 kb plus 5.3 kb (pattern 2). In *Taq*I digests of male DNA, λRC8 only hybridizes to two bands, the 6.6-kb fragment and either the 3.2-kb or the 5.3-kb fragment, never to three fragments. The nature of the polymorphic change has not been investigated but is irrelevant to the linkage analysis. It is only necessary that the alteration is stable and is inherited in a mendelian fashion.

Of a total of 26 *Taq*I-digested normal female and 23 normal male DNAs screened, 7 females were heterozygous (2/1) and 3 males had the rarer allele (2). All the other samples had the common allele (1). Calculated from the males, this gives a gene frequency for the rarer allele of 0.13 and is consistent with the *Taq*I polymorphism identified by λRC8 behaving as a single-copy X-chromosome sequence.

Families in which DMD occurred in at least two generations, and preferably with a living maternal grandfather, were identified from a register of DMD families in Wales, supplemented by families from other centres. Only those families in which the diagnosis was fully documented or which could be confirmed clinically were studied. Key obligatory carriers were first identified and blood samples taken. DNA was prepared, digested with *Taq*I and hybridized with radioactive λRC8 probe to determine which key carriers were heterozygous for the restriction fragment length polymorphism. If the key carrier was heterozygous, samples were collected from all other available informative members of the family. Sampling of female members was restricted to obligatory carriers; those females considered carriers on the sole basis of biochemical assay (serum creatine kinase) were excluded.

DNA from 45 unrelated obligatory carriers for Duchenne was digested with *Taq*I and screened with λ RC8; nine were heterozygous for the polymorphism, giving gene frequencies in the Duchenne carriers of 0.89 for allele 1 and 0.11 for allele 2. It is thus present at the same frequency in DMD families as in the control London population. The *Taq*I polymorphism was traced through nine families (Fig. 3) and is inherited in a mendelian fashion. Of 24 meioses, 21 retained linkage and 3 showed recombination.

Lod scores for the linkage between the polymorphism and the *DMD* locus (Table 1) were calculated using the LIPED computer program[18] and checked by hand. The overall probability of linkage is equivalent to the area beneath the curve of likelihood values at different genetic distances.

A lod score expresses in logarithmic form the probability that a linkage exists between two loci; for *DMD* and λRC8, the probability of linkage at a distance of ~10 centimorgans is 58:1 (making the assumption that linkage exists). The overall probability of any linkage is 22:1. The use of lod scores in this way is explained in detail by Race and Sanger[19]. From our experience, an analysis of at least 50 more obligatory carriers from well characterized DMD families would provide a further 10 informative pedigrees to confirm this assignment absolutely; therefore, we are making λRC8 available to others with access to DMD families.

DMD shows negative lod scores with colour blindness (Table 1). This is to be expected because colour blindness is within the *G6PD* linkage group on the end of the long arm of the X chromosome (Xq28)[20]. It provides a negative control and demonstrates the difference in lod scores between unlinked (but syntenic) and loosely linked loci. Using the Xg blood group, we have not yet studied sufficient informative families for λRC8 to obtain significant results, but clearly we have confirmed that there is no measurable linkage between *Xg* and *DMD*, thus confirming the exclusion of the terminal portion of the short arm of the X chromosome as the site of the *DMD* locus.

The results obtained suggest that the Duchenne locus is localized approximately in the middle of the short arm of the X chromosome. This supports data from six female cases of Duchenne muscular dystrophy with balanced *de novo* X-chromosome to autosome translocations with break points at Xp21 (refs 21, 22). As these data depend on an unequivocal clinical diagnosis of DMD in females, they have hitherto been regarded as highly suggestive rather than conclusive.

In this analysis, we have assumed that DMD is a single gene defect. As in the case of the β-globin gene locus in β-thalassaemia, it is possible that only a single locus is involved, but with several different molecular defects at that gene.

These data support the localization of the gene mutation causing Duchenne muscular dystrophy to the short arm of the X chromosome, and provide an example of how to use recombinant DNA technology to define linkage to a phenotype caused

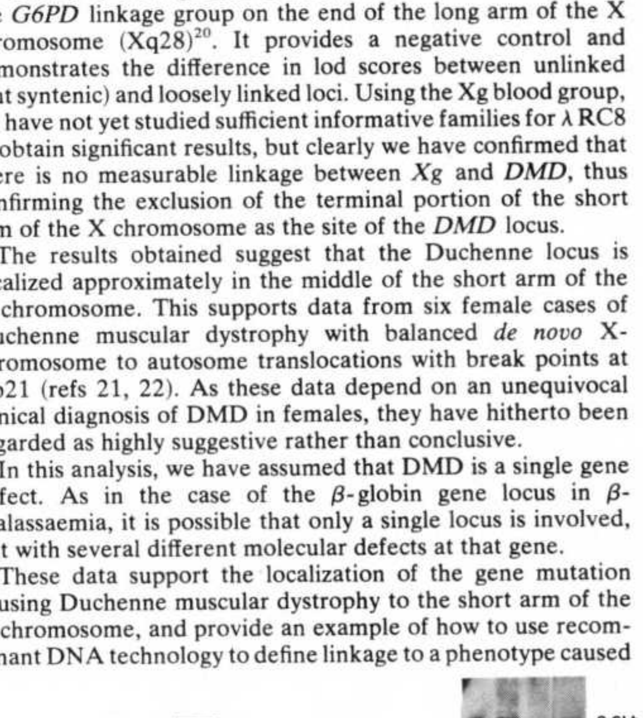

Fig. 3 Segregation of the λRC8 polymorphism through a DMD family showing the mendelian inheritance of the variant and also a cross-over between the two loci. Nine families were studied; full details are available from the authors. Symbols: square, male; black square, affected male; circle, female; dotted circle, obligatory carrier; oblique line through symbol, dead. The autoradiograph shows the hybridization of λRC8 to *Taq*I-digested DNA from members of the pedigree: *a*, grandfather; *b*, mother; *c*, *d*, sons.

by a single gene defect where the primary biochemical defect is unknown.

This work was supported by grants from the Cystic Fibrosis Research Trust, the MRC, the Muscular Dystrophy Group and a grant from the Deutsche Forschungsgemeinschaft to H. H. Ropers. We thank Hans Hilger Ropers and Peter Goodfellow for providing hybrid cell lines, David Hartley, Pauline Taylor and Rob Elles for probe characterization, Dr Mansoor Sarfarazi for LIPED computer analysis and Dr Tom O'Brien for help with sample collection and study of the families, Dr Ruth Sanger and Dr Patricia Tippett for performing the Xg analysis on DMD families, and the patients and their families for their cooperation; also the numerous clinicians who allowed us access to the patients under their care.

Anti-ovalbumin monoclonal antibodies interact with their antigen in internal membranes of *Xenopus* oocytes

G. Valle, E. A. Jones & A. Colman

Department of Biological Sciences, University of Warwick,
Coventry CV4 7AL, UK

The microinjection of selected antibodies into the cytosol or nucleus of living cells is proving a useful technique for investigating the function of intracellular proteins[1–5]. The rationale underlying this approach is that, in binding to its antigenic determinant, the antibody may mask or disrupt the activity mediated by the region of the protein near the determinant. This technique, however, cannot be used to identify functions related to antigenic determinants of proteins within the lumen of the endoplasmic reticulum (ER), or Golgi compartments, since both regions are inaccessible to direct microinjection and since the movement of proteins into these areas from the cytosol occurs during but not after their translation[6]. In theory, this constraint could be overcome if the mRNAs specifying the antibody were injected into the cell containing the target antigenic determinant. After the vectorial and co-translational transfer of its constituent chains through the membrane, the antibody would then be assembled within the lumen of the ER thereby being in a position to bind to its antigenic determinants. We demonstrate here a successful example of such an approach.

To study the interaction of antibody and antigen we made use of *Xenopus* oocytes. These cells will faithfully export secretory proteins after injection of the encoding mRNAs[7,8]. Additionally both assembly and secretion of a mouse immunoglobulin, MOPC 21, have been shown to occur normally in oocytes[9]. However, since the antigens recognized by this antibody are unknown, the biological activity of the oocyte product remains untested. Moreover, the oocyte might not possess the high levels of disulphide interchange enzyme thought to be necessary in immunoglobulin-producing cells for the production of correctly located S–S bonds within the immunoglobulin molecule[10]. In this letter we describe the synthesis in oocytes of murine monoclonal antibodies raised against chick ovalbumin, a protein whose synthesis and secretion from oocytes has been well characterized[11,12]. The antibodies synthesized by the oocyte maintain their specificity. When ovalbumin mRNA is also injected the formation of antigen–antibody complexes within the internal membranes of the oocyte results in a severe reduction in secreted antibody, even when the ovalbumin mRNA was introduced 24 h later.

Spleen cells from a BALB/c mouse immunized with ovalbumin were fused to P3-NS1 myeloma cells in the presence of polyethylene glycol[13]. The fusion was screened by an indirect trace binding assay[14] and positive wells cloned by the dilution method[15]. Two cloned hybridomas 7/2 and 3/4, both IgG_1, were chosen for the microinjection studies. Binding studies carried out under near-saturating conditions for both monoclonals and detecting antibody suggested that their binding was additive, indicating that they recognized different antigenic determinants on the ovalbumin molecule (data not shown). Furthermore, the stoichiometry suggested single antigenic sites on the molecule.

Immunoprecipitates of the immunoglobulin chains synthesized by the hybridoma cells had the same electrophoretic mobility as the analogous immunoprecipitated products made in oocytes after injection of the hybridoma mRNAs (Fig. 1*a*). Chick ovalbumin made by oocytes differs slightly in its post-translational modification from the oviduct protein[11]. Nevertheless the immunoglobulins made by the hybridoma cells bind to ovalbumin synthesized by oocytes after injection of oviduct mRNA (Fig. 1*b*).

Since the oligosaccharide moiety elaborated by oocytes for the glycosylation of immunoglobulins (A.C. and G.V., unpublished data) and other foreign proteins[16] differs from the 'native' side-chain, it was possible that the immunoglobulins synthesized by the oocyte would lack biological specificity. However, the monoclonal antibodies translated by the oocytes bound specifically to an ovalbumin immunoabsorbant (Fig. 1*c*).

The data above show that the monoclonal antibodies translated by oocytes and subsequently extracted will bind to ovalbumin. However, antibody conformation is dependent on correct disulphide bond formation. Since the exact redox potential within the ER of cells is unknown, and since disulphide bonds in immunoglobulins might be somewhat labile within the ER due to the presence of a disulphide-exchange enzyme[10], the biological activity manifested by the immunoglobulins after their extraction from oocytes might not exist in the intracellular environment. In order to examine this possibility we have injected various combinations of oviduct and hybridoma mRNAs into oocytes. The oocytes were incubated in medium containing ^{35}S-methionine for 24 h before oocytes and media were collected for analysis. Oocyte homogenates and media were immunoprecipitated with rabbit anti-chick ovalbumin or goat anti-mouse immunoglobulin antibodies, and the resulting immunoprecipitates examined by polyacrylamide gel electrophoresis (Fig. 2).

When the oocytes were injected with ovalbumin mRNA and both monoclonal mRNAs, the monoclonal antibody chains could be specifically precipitated by rabbit anti-ovalbumin (Fig. 2, track 3). Similarly, from the same oocytes, ovalbumin could be specifically precipitated by goat anti-mouse immunoglobulin (Fig. 2*b*, tracks 3 and 9). However, if only one monoclonal mRNA was co-injected with ovalbumin mRNA, this cross-precipitation effect was never observed although some non-

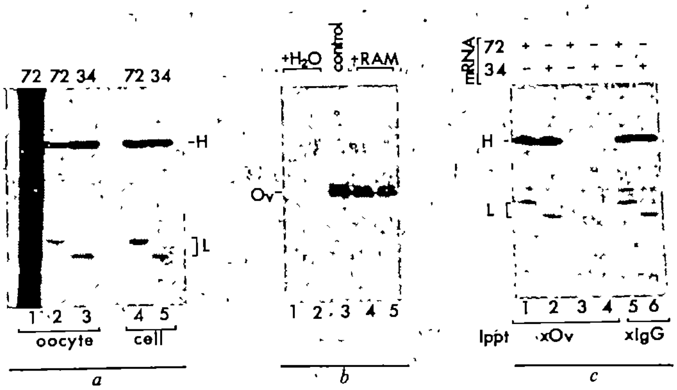

Fig. 1 Biological specificity of antibodies made by oocytes The 3/4 and 7/2 lines were grown in Dulbecco's modified Eagle's medium containing 10% horse serum (Difco) supplemented with hypoxanthine, aminopterin and tymidine Cells were labelled with ^{35}S-methionine (Amersham) as described by Cotton *et al.*[22] Media and cell homogenates were retained for immunoprecipitation and electrophoresis. Hybridoma mRNA was prepared by lysing 5×10^9 cells in hypotonic buffer containing 0 1% diethylpyrocarbonate (Sigma). The post-nuclear supernatant was twice phenol-extracted and then ethanol precipitated The RNA pellet was resuspended in 5 ml of 10 mM Tris-HCl *p*H 7.5, 1 mM EDTA, 0.1% SDS and 0.5 M LiCl, bound to oligo (dT) cellulose (Type III, Collaborative Research) and eluted with the same buffer minus LiCl. The polyadenylated mRNA was then ethanol precipitated and resuspended in distilled water at 1 mg ml^{-1}. Polyadenylated oviduct mRNA was prepared from laying Rhode Island Red hens as described by Palmiter[23]. For clarity this mRNA is referred to as ovalbumin mRNA in the text Oocytes were microinjected with 30 nl of mRNA and cultured in Barths saline (5 oocytes/30 µl) containing antibiotics, 6% fetal calf serum and 1 µCi µl^{-1} ^{35}S-methionine (300 Ci mmol^{-1}) for 24 h at 21 °C. Culture media were retained for electrophoresis whilst oocytes were homogenized in 100 mM NaCl, 1% Nonidet P40, 1 mM phenylmethylsulphonyl fluoride, 25 mM Tris *p*H 7.6 as previously described[7]. For electrophoresis the cell lysates, oocyte fractions and culture media were immunoprecipitated (see below) Precipitates were dissolved in sample buffer (20 mM Tris-HCl *p*H 9.2, 20% glycerol, 1 mM phenylmethylsulphonyl fluoride, 1% β-mercaptoethanol, 0 01% bromophenol blue and 2% SDS) and 25 µl aliquots were run on 12.5% polyacrylamide gels, followed by fluorography[24] Numbers above tracks refer to mRNA injected (oocyte) or cell lines used (cells). *a*, Synthesis and secretion of immunoglobulins by cells and oocytes. 50 µl aliquots of homogenates from mRNA-injected oocytes (tracks 2, 3) or labelled cells (tracks 4 and 5) were immunoprecipitated with 3 µl of goat anti-mouse IgG (Miles) using *Staphylococcus aureus* envelopes as previously described[9] Track 1 contains 5 µl of oocyte homogenate before immunoprecipitation. *b*, Ovalbumin made by oocytes binds to hybridoma antibodies Oocytes were injected with ovalbumin mRNA, labelled with ^{35}S-methionine and homogenized as described above. 50 µl of homogenate were mixed with 500 µl of immunoprecipitation buffer[9] and with 50 µl of hybridoma cell medium containing the monoclonal antibodies. The above mixture was incubated for 1 h on ice. Then either 10 µl of rabbit anti-mouse IgG (RAM) (tracks 4 and 5) or 10 µl of distilled water (tracks 1 and 2) were added and the incubation was continued for another 30 min on ice. Finally 50 µl of *S. aureus* suspension were added. The immunoprecipitation was completed as usual and samples run into a gel as described above and fluorographed. Track 1, 3.4 medium without RAM, track 2, 7 2 medium without RAM; track 3, control immunoprecipitated with rabbit anti-ovalbumin, track 4, 3.4 medium plus RAM, track 5, 7.2 medium plus RAM. Ov, ovalbumin. *c*, Oocyte anti-ovalbumin immunoglobulins bind to ovalbumin 50 µl aliquots of 10% *S. aureus* suspension in immunoprecipitation buffer were incubated with 3 µl of rabbit anti-ovalbumin (Miles, tracks 1–4) or with 3 µl of goat anti-mouse IgG (tracks 5, 6), for 30 min at room temperature in order to bind the antibodies to the bacterial envelopes The *S. aureus* envelopes were then spun and rinsed twice with 500 µl of immunoprecipitation buffer, resuspended in 500 µl of the same buffer and incubated for 30 min in presence (tracks 1, 2 and 5, 6) or absence (tracks 3, 4) of 0 2 mg ml^{-1} ovalbumin (Sigma) The envelopes were then rinsed twice as above and resuspended in 500 µl of immunoprecipitation buffer Meanwhile, homogenates were made from oocytes previously microinjected with 7.2 mRNA or 3.4 mRNA and subsequently labelled as in Fig. 2*a* 10 µl of oocyte homogenate were added to the appropriately prepared, resuspended envelopes and incubated overnight at 4 °C The rest of the immunoprecipitation and the electrophoresis weere carried out in the standard way described above. Ov, ovalbumin; H, immunoglobulin heavy chain, L, immunoglobulin light chain, Ippt, immunoprecipitation with rabbit anti-chick ovalbumin (xOv) or goat anti-mouse IgG (xIgG).

specific precipitation of ovalbumin occurred which disappeared if unlabelled ovalbumin was included in the homogenization medium (compare Fig. 2*b*, tracks 2–4 with tracks 8–10). This complex was not found when oocytes containing the two monoclonal antibodies and oocytes containing ovalbumin were mixed before homogenization (data not shown). We therefore interpret the co-precipitation of ovalbumin and the two monoclonal antibodies as indicating their association *in vivo* within the membraneous systems of the oocyte.

Figure 2 shows that the two monoclonal antibodies were also found associated with secreted ovalbumin present in the culture media (Fig. 2*a*, track 11; Fig. 2*b*, track 13). However, control experiments revealed that such association could take place in the media after secretion (data not shown) so it is not clear whether the monoclonal antibody–ovalbumin complex can be secreted.

The effect on secretion resulting from interactions between the immunoglobulins and ovalbumin was assessed by comparing the relative amounts of each protein inside and outside the oocyte under the different injection regimes. The results of some representative experiments are shown in Fig. 3*a*. Only ovalbumin and the two immunoglobulin γ chains were considered since excess light (k) chains are made and secreted by the oocytes (data not shown); these supernumerary chains will not be present in complexes between ovalbumin and tetrameric immunoglobulin. The results in Fig. 3*a* clearly show that not only was there a marked reduction of heavy chain secretion when both monoclonal antibodies were present with ovalbumin, but also when each immunoglobulin alone was present with ovalbumin. This latter result was surprising in view of our failure to detect any specific interactions by immunoprecipitation in these cases (see Fig. 2).

No significant reduction of ovalbumin secretion was seen or expected in these experiments, since only a small proportion of ovalbumin was bound to immunoglobulin inside the oocytes (see Fig. 3*c*).

We have recently demonstrated that MOPC 21 heavy (H) chain trapped in oocytes due to the absence of the complemen-

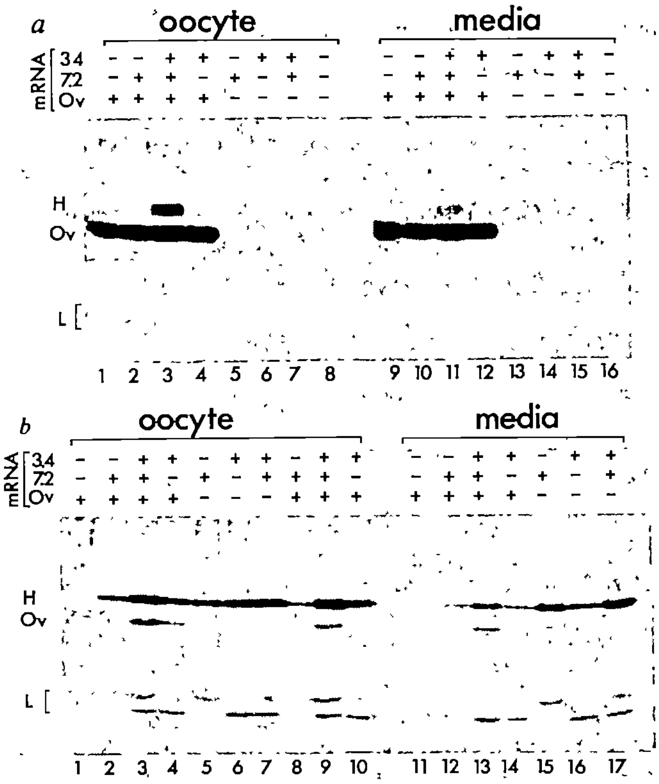

Fig. 2 Coinjection of ovalbumin and anti-ovalbumin mRNAs into oocytes. 7/2 mRNA (0.3 mg ml^{-1}), 3/4 mRNA (0.3 mg ml^{-1}) and ovalbumin mRNA (0 04 mg ml^{-1}) were injected as indicated above into oocytes Oocytes were cultured as described in Fig. 1 and processed for immunoprecipitation with rabbit anti-ovalbumin (*a*) or goat anti-mouse (IgG) (*b*) antibodies In *b* tracks 8–10 homogenization and immunoprecipitation media were supplemented by the addition of unlabelled ovalbumin to 1 mg ml^{-1} final concentration Immunoprecipitates were electrophoresed on 12.5% PAGE gels under reducing conditions and then fluorographed Ov, ovalbumin, H, immunoglobulin heavy chain; L, immunoglobulin light chain.

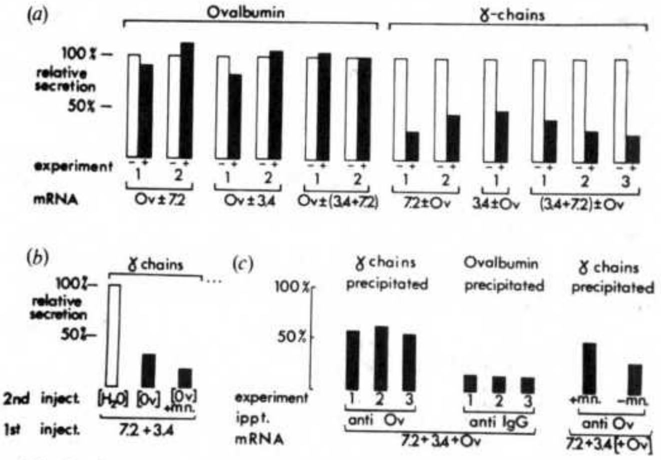

Fig. 3 Quantification of the interactions of monoclonal antibodies with ovalbumin. *a*, Comparisons of the ratios of secreted to intracellular ovalbumin or immunoglobulin γ chains. Appropriate bands from the gels shown in Fig. 2 and other similar experiments were excised and counted in toluene-based scintillant. Corrections were made for radioactivity migrating in the corresponding regions of control tracks. The ratios of secreted to intracellular protein were calculated, converted to percentages and adjusted to 100% for the controls (open blocks) where only one mRNA class (hybridoma or oviduct) was injected. Stippled blocks indicate the injection of both mRNA classes. *b*, Staggered mRNA injection. Appropriate bands from the gel shown in Fig. 4 were treated as above. The mRNAs introduced in the second injection are shown in square brackets. mn, Monensin. *c*, Degree of co-precipitation. The amounts of intracellular ovalbumin or immunoglubulin γ-chain immunoprecipitated with each antibody was calculated by excising gel bands from tracks corresponding to oocyte samples where ovalbumin mRNA, 7/2 mRNA and 3/4 mRNA had been co-injected (for example, Fig. 3, tracks 3; Fig. 5*b*, tracks 12, 13). The amount of the γ chains or ovalbumin which co-precipitated with rabbit anti-ovalbumin or goat anti-mouse IgG respectively is expressed as % of the total amount of each protein directly precipitated by its antibody. The two blocks on the right of this figure correspond to the staggered injection experiment of Fig. 4 with the second mRNA shown in square brackets. mn, Monensin; ippt, immunoprecipitating antibody. When the immunoglobulin tetramers were excised from a non-reducing gel and re-electrophoresed under reducing conditions, band analysis revealed that the heavy chains contained 4–5 times more radioactivity than the light chains. This indicates that the γ-chain contains 4 or 5 methionines or multiples thereof. Using this information and the calculated radioactive contents of γ-chain and ovalbumin (16 methionines) bands in the experiments above, we estimate there to be 1.5 times (or multiples thereof) more ovalbumin than γ-chain in the oocytes.

tary light (L) chain can be rescued by assembly into an H_2L_2 tetramer as a result of an injection of light chain mRNA 24 h later[17]. We were therefore interested to see whether any of the radioactive immunoglobulin molecules remaining in injected oocytes 12 h after the imposition of unlabelled methionine 'chase' conditions were accessible to ovalbumin molecules translated from a post-chase injection of oviduct mRNA. Figure 4 illustrates such a staggered injection experiment. Quantitation of the results shown in Fig. 4 demonstrates first that immunoglobulin secretion was reduced by 60% in the presence of ovalbumin (Fig. 3*b*) and second that when homogenates of such double-injected oocytes were precipitated with rabbit anti-ovalbumin, 29% of the intracellular γ chain co-precipitated, a somewhat lower proportion than the 60% found when the two mRNAs were co-injected (Fig. 3*c*). This value increased to 49% if secretion was further inhibited (Fig. 4, tracks 5 and 6) by use of the ionophore monensin, an agent known to inhibit secretion[18,19] by disrupting the Golgi apparatus[20].

The anti-ovalbumin monoclonal antibodies synthesized by oocytes are clearly specific for ovalbumin after their individual extraction from oocytes. In contrast, intracellular interaction, as identified by immunoprecipitation, between the monoclonal antibodies and ovalbumin can only be shown when both antibodies are present. This might be a consequence of the low affinity of these particular antibodies for their antigenic determinants. Since the two antibodies recognize different determinants an aggregate between ovalbumin and the antibodies is expected. The formation of an aggregate might consolidate the weak interactions between individual molecules[21]. Under

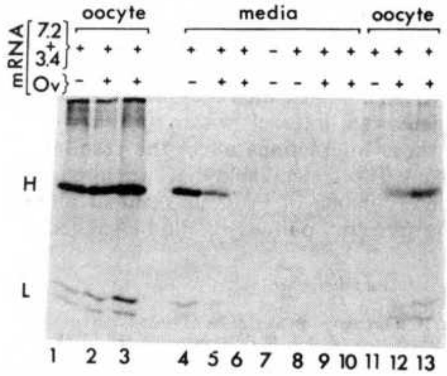

Fig. 4 Staggered injection of ovalbumin and anti-ovalbumin mRNAs. Oocytes were injected with 7/2+3/4 mRNA (both at 0.3 mg ml⁻¹) and immediately cultured overnight in media containing ³⁵S-methionine with (tracks 3, 6, 10, 13) or without 30 μM monensin (Calbiochem). Healthy oocytes were transferred to unlabelled media supplemented with 10 mM methionine for a further 12 h. Ovalbumin mRNA (1 mg ml⁻¹) was then injected into some oocytes and incubation continued for 24 h. Oocytes and media were immunoprecipitated with goat anti-mouse IgG (tracks 1–7) or rabbit anti-ovalbumin (tracks 8–13) antisera and electrophoresed on a 12.5% gel. A 4-day fluorogram is shown. Ov, ovalbumin; H, immunoglobulin heavy chain; L, immunoglobulin light chain.

these circumstances secretion of the tetrameric immunoglobulin was significantly reduced. This is not particularly surprising considering the potentially large size of the aggregate. What is surprising, however, is the reduction of immunoglobulin secretion when only one antibody is present. This reduction is not due to competition with the ovalbumin for some limiting oocyte component necessary for translocation since we have previously demonstrated that mRNA transition itself is the only process which limits the export of secretory proteins from oocytes[11]. Additionally, secretion from oocytes of a murine anti-membrane protein antibody was unaltered by the presence of ovalbumin (Fig. 5). More likely, the reduction of secretion is due to the existence of an equilibrium between slow or unmoving antibody–$(\text{ovalbumin})_2$ trimers and the individual molecules. Even so it is unclear why the movement of such trimers would be reduced unless a conformational change induced by binding in either antigen or antibody is incompatible with the secretory mechanism.

The demonstration that ovalbumin introduced via mRNA injection into oocytes already containing the anti-ovalbumin immunoglobulins can associate with some of the intracellular immunoglobulin indicates that secretory proteins whose

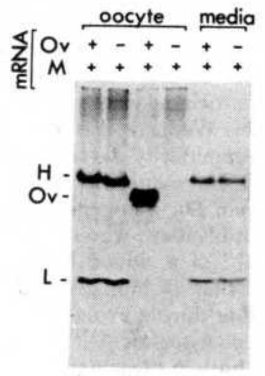

Fig. 5 Secretion of ovalbumin and anti-*Xenopus* immunoglobulins from oocytes. Total RNA was prepared from the murine hybridoma line 18H-11 as described in Fig. 1. This hybridoma secreted an antibody which reacts with a *Xenopus* membrane antigen (E. Jones, unpublished). The RNA at 2 mg ml⁻¹ and ovalbumin mRNA (0.06 mg ml⁻¹) were injected into oocytes and the culture, processing of oocytes and media, and electrophoresis as in Fig. 2. Ov, ovalbumin; M, RNA from 18H-11; H, immunoglobulin heavy chain; L, immunoglobulin light chain; Ippt, immunoprecipitation with rabbit anti-chick ovalbumin (xOv); goat anti-mouse IgG (xIg).

synthesis is temporally separated, can nevertheless become spatially apposed. However, the intracellular location for this interaction remains undetermined.

Thus we have demonstrated that monoclonal antibodies and their antigens can interact within the ER of the oocyte. Evidently these interactions affect the resultant secretion of these proteins. It is conceivable that the function of luminally-exposed determinants of proteins resident along, or passing through the secretory pathway could be gauged by the disruptive effects of introducing monoclonal antibodies raised against them. There seems no reason why this approach cannot be extended to microinjection of cultured cells where the possibilities of combining immunofluorescent and biochemical techniques would facilitate analysis.

We thank Daniel Cutler for the gift of ovalbumin mRNA, and S. Bhamra and A. Rughani for technical assistance. This research was supported by the Cancer Research Campaign (A.C. and G.V.) and the MRC (E.J.).

A cDNA sequence encoding a rabbit heavy chain variable region of the V_Ha2 allotype showing homologies with human heavy chain sequences

K. E. Bernstein, E. Premkumar Reddy*, C. B. Alexander & R. G. Mage

Laboratory of Immunology, National Institute of Allergy and Infectious Diseases, and * Laboratory of Cellular and Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

There are only four positions in the amino acid sequences of immunoglobulin variable region domains of all species at which the same amino acid is always found[1]. The compiled sequences of rabbit heavy chain variable (V_H) domains have 48 invariant positions[1,2] and at 14 additional positions in the first and third framework segments the different amino acids found correlate with the rabbits' V_Ha allotype[3–5]. This V_H allotypic system with three common 'alleles' *V_Ha1*, *V_Ha2* and *V_Ha3* inherited in simple mendelian fashion[3,4] poses the question of how gene families with distinct sets of conserved codons have evolved and been maintained in the midst of information leading to hypervariability. Here we report a cDNA sequence that encodes a protein characteristic of the rabbit V_Ha2 allotype and we predict the allotype-associated codons that may be found in *V_Ha1* and *V_Ha3* genes. We have also found within the second hypervariable, complementarity-determining region (CDR2) encoded by our cDNA clone, a DNA sequence highly homologous to a human D_H minigene[6]. This observation and a similar one of Wu and Kabat[7], who identified a D_H minigene sequence in the CDR2 of a cloned human V_H gene[8], lends support to their idea that *D* minigene information has contributed to CDR2 either during evolution or ontogeny[7]. Gene conversion[9,10], minigene assortment[11,12] or insertion[13] mechanisms may be involved both in the generation of hypervariability and the conservation of allotype codons.

A partial cDNA library from splenic mRNA of V_Ha2 rabbits infected with *Trypanosoma equiperdum* was the source of clone pμ3. This cDNA clone is a full-length copy of mRNA encoding the hydrophobic leader, V_H and C_H regions[14]. DNA was sequenced by the procedures of Maxam and Gilbert[15]. The variable region restriction map and our sequencing strategy are shown in Fig. 1. Figure 2*a* shows the nucleotide sequence and the deduced amino acid sequence of the variable region of pμ3.

There are no rabbit nucleic acid sequences of cDNAs or genomic V_H, D_H or J_H genes with which to compare our sequence, but we found considerable homology with a cloned human genomic V_H segment, V_H26 (ref. 8) and with the human J_H4 minigene segment[16] and show these for comparison in Fig. 2*a*. Different genomic sequences for human *J* segments encode 15–17 amino acids and through comparison with human J_H4 it is probable that the Phe (TTC) at amino acid position 100C of pμ3 was contributed by a codon from a *J* minigene. The Phe (TTT) preceding it could have been *D*- or *J*-encoded or the site of intracodon recombination between *D* and *J*. The D portion of pμ3 appears to encode seven or eight amino acids (positions 95–100A or 100B) and the sequence encoded bears no resemblance to any published rabbit protein sequences in this region[1,17]. The nucleic acid sequence of our rabbit V_H (Fig. 2*a*) is remarkably homologous to the human V_H26 sequence (73% in the leader and V_H amino acid positions −20 to +94) and to the human J_H4 minigene (80% homology for amino acid positions 100C–113). A striking and unexpected degree of homology is found in the CDR2 of these two sequences. Introduction of a codon gap at amino acid position 52 and deletion of two codons at positions 55 and 56 in the rabbit sequence allows alignment of 17 of 18 bases within this 'hypervariable region'. This is precisely the part of the human CDR2 (amino acid positions 52A–56) in which Wu and Kabat found a sequence of 14 nucleotides homologous to the human *D2* minigene[7]. These 14 nucleotides are enclosed in a box in Fig. 2*a*. As shown in Fig. 2*b*, we find a similar homology although to a lesser degree when the rabbit sequence between the codons for amino acids 49 and 59 is compared with human V_H26 and the human *D1* and *D2* minigene sequences[6]. These observations lead one to ask how it is that a sequence homologous to a *D* minigene is found in the CDR2 of both rabbit and human V_H regions. In mice the hypervariability of the third CDR results from rearrangements that join DNA segments coding for V_H, D_H and J_H during B lymphocyte differentiation[18,19]. The genetic basis of hypervariability of the first and second complementarity-determining regions (CDR1 and CDR2) is less well understood. Wu and Kabat have suggested an insertion mechanism for the generation of hypervariable region diversity[13]. Indeed, the portion of CDR3 encoded by one or more D_H segments of mice is such an insert[18,19]. The present observations lend further but indirect support to the idea that *D* minigene information has somehow contributed to the sequence of the second CDR either through mechanisms of gene conversion[9,10], minigene assortment[11,12] or insertion[13].

The number of J_H genes present in the rabbit genome is unknown. However, published protein sequences that include the segment presumed to be encoded by the J_H segment show

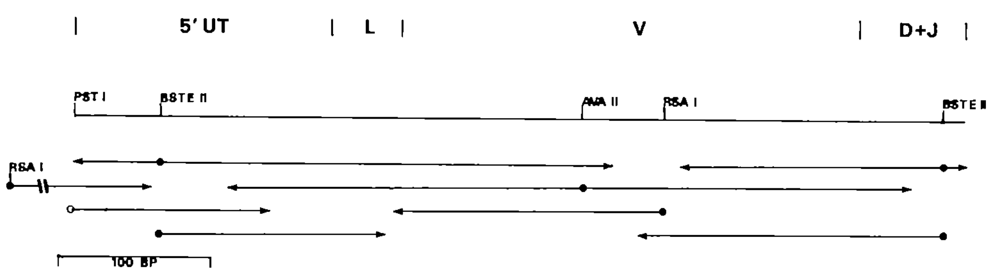

Fig. 1 Strategy used in sequencing the DNA of clone pμ3. The top of the figure indicates the relative sizes of the 5′ untranslated region (5′ UT), the leader sequence (L), the variable region proper (V) and the D and J segments. All sequencing was done using the method of Maxam and Gilbert[15]. Solid and open circles indicate fragments 5′ or 3′ labelled, respectively. The arrows and lines show the length and direction of sequencing. The *Rsa*I site in pBR322 at position 3,847 was also used. The relative size of 100 base pairs (bp) is indicated.

little deviation from a prototype sequence between positions 101 and 113[2,17]. Clone pμ3 encodes the 11 invariant amino acids at positions 103–113 but has Ala replacing Asp and Ile replacing Val at 101 and 102. Whether this is due to a different germ-line *J* segment, somatic mutation or some other mechanism is unknown. The usual Asp and Val can be arrived at by single base changes from the GCC and ATC we observed in clone pμ3.

In our V_H sequence, unusual amino acids are found at positions 93 and 94. This is a highly conserved area of the V_H region and in all other published sequences of rabbit V_H, the amino acids at positions 93 and 94 have been alanine and arginine. Clone pμ3 encodes Gly and Ser at these positions; the sequence was confirmed on both strands. The Gly and Ser codons (GGG, AGT) are potentially derived by single base changes from codons for Ala (GCG) and Arg (CGT). According to Kabat *et al.*[1], of 73 published sequences of V_H regions from all species, 64 have Ala at position 93; Gly has not been reported before. Similarly, 54 of 73 V_H sequences have Arg at position 94 with one reported Ser.

With the exception of the Ala and Arg at 93 and 94 and a deletion at position 2 that is found in 12 of 14 rabbit V_H sequences, each of the 33 other invariant residues listed by Kabat *et al.*[1] are encoded by pμ3. The same pattern is found when considering the amino acids that are thought to comprise the V_Ha allotypes. Although relatively few rabbit V_H proteins have been sequenced, sequence comparisons suggest that the amino acids determining a particular V_Ha allotype are clustered in FR1 and FR3 (positions 5–17 and 65–85). Figure 3*a* summarizes the positions at which V_Ha allotype-associated amino acids occur. Comparison of our deduced amino acid sequence for these positions with known V_H protein sequences clearly shows that clone pμ3 encodes a V_H sequence characteristic of the a2 allotype. As shown in Fig. 3*b*, with two exceptions (a2 Asp to a1 Thr at position 16 and a2 Gly at position 84 to a1 Thr), the codons of pμ3 found at allotype-associated positions can theoretically be changed by one base to give a codon for the amino acids typical of the a1 and a3 allotypes. The codons predicted to occur in a1 and a3 are also compared with those found in the human V_H26 gene (Fig. 3*b*). The codons of V_H26 match the predicted codons at 6 of the 14 positions compared and two additional codons differ only in the third base. Although there have been no confirmed reports of V_Ha-like alleles in man, some rabbit anti-a1 allotype antibodies do react with some human immunoglobulins but do not detect a polymorphic system[20]. The present comparison of the allotypic regions of rabbit with human V_H suggests that 'allelic' variants could occur in man.

It has been suggested that rabbits of different 'allelic' V_Ha phenotypes share the same set of coding sequences but have different allelic regulatory elements[21]. Observations of occasional production of unexpected V_Ha allotypes (for example, V_Ha2 in an a^1a^3 rabbit[22]) have supported such suggestions[22,23]. Our data show that certain portions of the rabbit V_H sequence are highly conserved even between species. Thus a truly allotype-specific V_H probe for investigation of this problem will not be a simple one to design. Clone pμ3 constructed from mRNA of V_Ha2 animals encodes a typical a2 protein sequence and thus provides a means for investigating the genetic basis of the rabbit V_Ha allotypes and solving the paradox of conserved V_H gene families intimately associated with mechanisms that lead to hypervariability.

We thank Myron Waxdal for help with our computer analyses, Dr T. T. Wu who provided computer printouts from his

Fig. 2 *a*, The nucleic acid sequence and deduced amino acid sequence of the region of clone pμ3 encoding the leader (L), V_H, D_H and *J* segments of a rabbit V_H domain are compared with the human genomic V_H26 (ref. 8) and the human J_H4 (ref. 16) sequences. The amino acid position numbers are those of the standard numbering system of Kabat *et al.*[1]. A sequence of 14 nucleotides in V_H26 that is homologous to 14 bases in the human *D2* minigene is enclosed in a box. The intron between L and V in V_H26 is omitted. Splicing of L to V is believed to occur within Gly −4 (ref. 8). *b*, Comparison of sequences corresponding to amino acid positions 49–59 of rabbit and human V_H sequences in which homologies to human *D* gene sequences are found. The putative *D*-encoded portion of the CDR3 of pμ3 (amino acid positions 95–100A or 100B) is shown in *a*.

Fig. 3 *a*, Sequences of rabbit V_H proteins of known V_Ha allotype are compared with the deduced amino acid sequence encoded by clone pμ3 in the parts of the first and third framework segments (FR1 and FR3) in which allotype-associated amino acids are found. The sequences are from ref. 1, in which references to the original papers are also given. The amino acids at positions implicated as V_Ha allotype correlates are shown in capital letters. The amino acid sequence encoded by the human *V_H26* gene is also shown for comparison. Solid lines indicate identity to the a2 or a1 prototype sequences. *b*, The codons at amino acid positions implicated as V_Ha allotype correlates found in clone pμ3 (V_Ha2) are compared with hypothetical codons (enclosed between brackets) that would generate amino acids typically found in a1 and a3 proteins. Also compared are the homologous codons found in the human *V_H26* gene sequence. Dashes indicate bases that are identical to those shown for pμ3. Boxes enclose codons in the human *V_H26* sequence and hypothetical a1 and a3 sequences that are identical at all or the first two bases. A one-base change to AGC would also generate a Ser codon at position 17 of *V_Ha3* sequences.

database, Shirley Starnes for typing the manuscript and our many colleagues at NIH for helpful comments. In addition we made use of The National Biomedical Research Foundation's Nucleic Acid Sequence Database and computer system. K.B. especially thanks Ellen Nielsen for help.

Domain structure in high molecular weight high mobility group nonhistone chromatin proteins

Gerald R. Reeck*, Paul J. Isackson*
& David C. Teller†

* Department of Biochemistry, Kansas State University, Manhattan, Kansas 66506, USA
† Department of Biochemistry, University of Washington, Seattle, Washington 98195, USA

The high mobility group (HMG) proteins[1] are a small set of nonhistone chromatin proteins which exhibit preferential affinity for single-stranded DNA[2–4]. Large portions of the amino acid sequences of calf thymus HMG-1 and HMG-2 have recently been published[5]. We have analysed that information and describe here an internal sequence homology in the proteins which, coupled with a prediction of secondary structure, strongly suggests that all the high molecular weight HMG proteins (HMG-1, HMG-2 and HMG-E) exist in three domains of comparable lengths. The N-terminal and central domains have homologous sequences and are probably similar in conformation. The C-terminal domain is nonhomologous and highly acidic. We also present results of trypsin digestion experiments which are consistent with the postulated domain structure. We propose that the N-terminal and central domains of the proteins are DNA-binding regions and that the highly acidic C-terminal domain interacts with histones.

In our first analysis, we have used amino acid sequence comparison methods developed in one of our laboratories[6], which we have previously used on histones[7]. The methods are an adaptation of procedures described by Sankoff[8] for comparison of nucleic acid sequences. The Sankoff algorithm finds optimal alignments of two sequences (or families of sequences in our case) under a specified constraint on the maximum number of gaps. The statistical significance of an alignment proposed on the basis of the Sankoff algorithm is assessed by comparing the scores of the proposed alignment with the scores of alignments between pairs of randomized sequences[7,9]. We have used the scheme of McLachlan for scoring similarities between amino acid residues[10].

HMG-1 and HMG-2 have sufficiently similar amino acid sequences that an alignment between them, as previously published by Walker *et al.*[5], is unambiguous. We therefore treat them as a two-member family[10,11] of homologous sequences, designated HMG-1,2. We have found an internal homology in HMG-1,2 by examining the first two 100-residue portions of the family's sequence. Figure 1 shows an alignment between positions 1–92 and 98–176. The one gap is needed to optimize the alignment before and after a stretch of unknown sequence (positions 40–54). The alignment score in Fig. 1 is 1,079 in the McLachlan scoring scheme as we use it[6]. To assess the statistical significance of the alignment, the Sankoff algorithm was applied to 100 pairs of randomized sequences identical in length and amino acid composition to the sequences of positions 1–97 and 98–189. The scores of the optimized alignments (with one gap allowed) between the pairs of randomized sequences had a mean of 604 and a standard deviation of 57; the highest score observed was 723. Performing more randomizations seemed superfluous, given the large separation between the score of the proposed alignment and the scores of the alignments of randomized sequences. With the data from 100 randomizations, we are limited to concluding[12] that the level of significance of the alignment in Fig. 1 is less than 0.01. The level of significance is, in fact, much lower than 0.01. Although the distributions of scores from comparisons of randomized amino acid sequences are in general not gaussian, for relatively long sequences such as we consider here, the distribution of scores is reasonably close to gaussian[6]. Assuming a gaussian distribution, the proba-

Fig. 1 Internal homology in HMG-1,2. The amino acid sequences of HMG-1 and HMG-2 were treated as a two-member family and numbered as in ref. 5. The sequence at positions 40–53 and at position 165 is unknown (×). The single gap in the alignment is indicated by a series of dashes. The Sankoff algorithm was applied to the first two 100-residue portions of the family's sequence to produce the alignment shown. The 25 positions in the alignment at which the McLachlan score was from 7 to 10 (that is, positions where strong similarity exists between amino acid residues) are indicated by solid lines. The 15 positions at which weaker similarity exists (McLachlan scores of 5 or 6) are indicated by broken lines. Of the remaining 30 aligned positions, only 8 had McLachlan scores less than the average score of 4 obtained by pairwise comparison of all positions in the first homology region with all positions in the second homology region. There are apparently more residues in the stretch of unknown sequence (positions 39–54) in the first homology region than in the corresponding portion of the second homology region (positions 130–139). Thus, when the entire sequence of HMG-1,2 is determined, a gap will be necessary in the second homology region to optimize the entire alignment. In the meantime, we have arbitrarily placed positions 130–139. When allowed two gaps, the Sankoff algorithm introduces a five residue gap in the second homology region after position 164, but without a statistically significant increment[6] in score. We therefore present the one gap alignment.

Table 1 Amino acid composition of fragment P3

The analysis of P3 was performed after 22 h of hydrolysis at 110 °C in 6 N HCl. No corrections have been made for partial destruction of Thr, Ser, Cys or Tyr. Trp was not determined. The amino acid composition of the N-terminal 92 residues of HMG-1 was calculated from the amino acid sequence of HMG-1 (ref. 5).

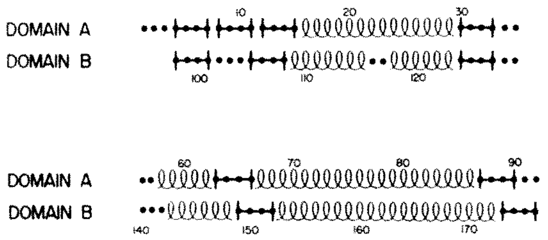

Fig. 2 Predicted secondary structure in domains A and B of HMG-1. The two portions of HMG-1 are aligned as in Fig. 1. Secondary structure, predicted by the rules of Chou and Fasman[17], is shown only for the positions that are paired in Fig. 1. Residues predicted to occur in α-helices are shown as ℓ. •, Nonhelical residues. Sets of four residues predicted to occur as β-turns (probability $p_t \geq 1.2 \times 10^{-4}$) are shown as solid lines. β-sheet potential exists in several short stretches in the HMG-1 sequence, but is not strong enough or does not extend long enough to over-rule α-helical potential in the same regions. The similarities in the predicted secondary structures of domains A and B extend, in the following ways, beyond those that are obvious from the diagram. (1) A third β-turn is predicted in the initial portion of domain B, but is not shown because it has a probability, $p_t = 1.1 \times 10^{-4}$, somewhat lower than the cut-off probability we used for predicting β-turns. In addition, that predicted turn overlaps at residue 101 with the turn predicted in domain B at residues 98–101. (2) The first predicted helical region in domain B is interrupted at positions 116 and 117. A corresponding weakness in the predicted helix occurs in domain A at residues 21–23: the helical potential of those residues is just above the threshold for helix termination. In these positions in each domain, there is β-turn potential, but with probabilities below our cut-off. (3) Residues 36–39 in domain A and residues 130–139 in domain B are not shown in the diagram because they are not aligned in Fig. 1; each region is, however, predicted to be helical. (4) A β-turn is predicted at positions 170–173 in domain B at a probability of 1.25×10^{-4}. The turn, which would correspond almost precisely with a turn predicted in domain A, is not shown because it overlaps with the turn predicted at positions 173–176, which has a higher probability. A similar case holds at positions 146–149 in domain B. Finally, note that positions 55–57 are predicted to be nonhelical because the residues there (Arg, Trp and Lys) all occur with high frequency in nonhelical regions adjacent to N-terminal portions of helices[17]. The final prediction at those positions could be affected by the identity of residues, now unknown, at positions 39–54 in the sequence of HMG-1.

bility of obtaining a score by chance that is 8.3 or more standard deviations from the mean [(1,079–604)/57 = 8.3] is 10^{-16} (obtained by interpolation of data compiled in ref. 13). This very low apparent probability emphasizes that the alignment in Fig. 1 is statistically highly significant.

Much of the sequence of the final portion (positions 177–259) of HMG-1,2 is not yet determined. However, that which has been sequenced is extraordinarily acidic. In HMG-1, over 50% of the positions sequenced are either Glu or Asp[5], and a continuous stretch of 41 acidic residues has been reported[14]. Clearly, the final third of HMG-1,2 is not homologous in amino acid sequence with the two regions shown in Fig. 1.

The above analysis suggests a domain structure for HMG-1 and HMG-2 and, presumably, for the homologous[15] HMG-E. We propose that all the high molecular weight HMG proteins consist of three domains. In HMG-1,2, the first domain, domain A, extends from position 1 to position 92. Domain B, which is homologous in sequence to domain A, corresponds to positions 98–176. Positions 93–97 (Lys-Lys-Lys-Phe-Lys in HMG-1) connect the first two domains. Domain C is the highly acidic C-terminal third of the proteins (positions 177–259). Domains A and B carry a net positive charge at neutral *p*H. In HMG-1, the number of Lys and Arg residues exceeds the number of Asp and Glu residues by 12 and 6 in domains A and B respectively. Domains A and B therefore seem well suited to be DNA-binding domains. Because they contain a normal complement of hydrophobic residues, these domains appear likely to occur in compact, globular conformations. Domain C, with its extreme content of acidic residues and paucity of hydrophobic residues (only six with marked hydrophobic character), presumably occurs as a coil, without organized folding. One would not expect it to bind to DNA and that expectation is supported experimentally[16]. Domain C seems to be designed, instead, to interact electrostatically with positively charged molecules such as histones. It is noteworthy that polyglutamic acid is capable of facilitating the assembly of core histones and DNA into nucleosomes[17].

By applying the Chou and Fasman prediction rules[18] to the sequences of domains A and B, we can predict their secondary structures. The predictions are strikingly similar for the two putative domains (Fig. 2). Each is predicted to have a substantial content of α-helix, in corresponding positions, and no β-sheet. The prediction is therefore consistent qualitatively with estimates of secondary structure in HMG-1 from circular dichroism measurements[16,19]. The similarities in predicted structure extend to the positions of β-turns, even though the residues involved in corresponding predicted β-turns are not generally conserved in sequence between the two homologous regions.

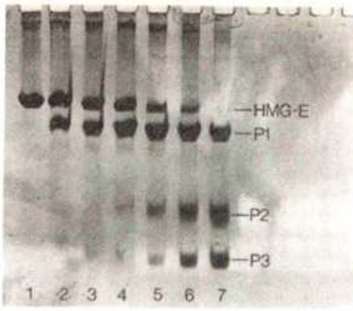

Fig. 3 Acid/urea polyacrylamide gel electrophoresis of the products of trypsin digestion of chicken erythrocyte HMG-E. HMG-E was purified by phosphocellulose chromatography[21] of a 0.35 M NaCl extract of chromatin. The digestion was carried out at 0 °C in 0.1 M NaCl, 10 mM Tris-Cl, *p*H 7.5 with HMG-E at 25 $\mu g\ ml^{-1}$ and trypsin at 0.25 $\mu g\ ml^{-1}$. At the following times (min) aliquots were removed from the reaction mixture and samples prepared for electrophoresis as previously described[4]: 0 (track 1), 2 (track 2), 5 (track 3), 15 (track 4), 30 (track 5), 60 (track 6) and 120 (track 7). Material cleaved from HMG-E in forming P1 has not been detected on either acid/urea or SDS-polyacrylamide gel electrophoresis, perhaps because of failure to react with Coomassie blue or because of rapid diffusion from gels during staining or destaining.

Apart from X-ray crystallographic structure determination, the most direct experimental evidence for domain structure in proteins is the production, by limited proteolysis, of large, discrete fragments that are soluble in aqueous solvents. We have observed such fragments by treating individual high molecular weight HMG proteins with trypsin. Figure 3 shows an electrophoretic analysis of products of the trypsin cleavage of chicken erythrocyte HMG-E. Trypsin digestion mixtures have been subjected to chromatography on phosphocellulose and DNA–cellulose. P1, P2 and P3 are all water-soluble, DNA-binding proteins. We have purified P1 and P3 for analyses. P1 has a molecular weight of 19,000, as determined by sedimentation equilibrium in the analytical centrifuge. The molecular weight of P3 has been estimated to be 10,500 (by SDS-gel analyses) and 10,100 (by sedimentation equilibrium). P1 and P3 both have the same N-terminal amino acid sequence as the parent protein, HMG-E[20]. (Ten residues were identified in HMG-E, in P1 and in P3 by automated Edman degradation.) P1 thus corresponds to domains A and B linked together, and P3 to domain A alone (Table 1). It has not yet proved possible to obtain P2 in sufficient purity or yield for analysis. Because P2 appears in comparable amounts to P3 and with the same time course as P3, and because P2 has a molecular weight of about 10,000 (by SDS-gel analysis), P2 probably corresponds to domain B.

The trypsin digestion results are thus consistent with our postulated three-domain structure for the high molecular weight HMG proteins. Studies of the structure and DNA-binding properties of the trypsin-generated fragments should provide insights into the role of the intact proteins in chromatin structure and function.

We thank Dr George Long for supplying a program for the Chou and Fasman prediction rules, and M. Daniel Land, David Manning, Lisa Wen and William Debold for assistance in some of the experiments. Electron microscopic localization of the replication origin of *Euglena gracilis* chloroplast DNA

P. Ravel-Chapuis, P. Heizmann & V. Nigon

Département de Biologie Générale, Université Claude Bernard
Lyon-I, F-69622 Villeurbanne Cedex, France

Chloroplast DNA (ctDNA) generally occurs as circular molecules with molecular weights (MWs) in the range $70-130\times10^6$ depending on the species[1,2]. In *Euglena gracilis*, ctDNA (44 µm, 92×10^6 MW[3]) replicates through Cairns-type intermediates[4] having structural aspects suggesting bidirectional replication[5]. Pea and corn ctDNA were shown to contain two displacement loops (D-loops) located 7,100 base pairs (bp) apart[6]. The displacing strands of the two D-loops are located on opposite strands of the parental DNA; they expand towards each other and form a Cairns replicative intermediate when the two strands elongate past each other. Rolling circle intermediates[7], apparently resulting from the continuation of Cairns rounds of replication, have also been observed[8]. The origins of replication were not located on physical maps for any of these studies. We present here the results of an electron microscopic (EM) study indicating that replication of ctDNA in *Euglena* is initiated near the 5′ end of the supplementary 16S ribosomal RNA gene[9].

Replicating ctDNA was extracted from *Euglena* cells synchronized by light–dark cycles (12 h/12 h)[5] (Fig. 1). The highest yields of replicating molecules (up to 20% of the circular molecules) were obtained from cells collected in the middle of the light phase (compare with results of refs 5, 10). The replicated fraction of the various molecules represented from 1 to 80% of the total genome length.

When replicating ctDNA was digested with the restriction endonuclease *Pvu*II, replication loops were observed on fragments 22.4 ± 0.3 µm long ($n=31$ molecules) (Fig. 1*a*, *b*) corresponding to the fragment *Pvu* A (67 kilobase pairs, kbp; Fig. 2). After *Xho*I digestion replication loops were localized on fragments 16.2 ± 0.3 µm long ($n=14$) (Fig. 1*c*) corresponding to the fragment *Xho* A (49 kbp; Fig. 2). These observations, taken together show that replication is initiated in the region common to *Pvu* A and *Xho* A fragments, that is, in the region 5′ to the ribosomal cistrons (see physical map; Fig. 2). To ascertain this localization, R-loops were formed by hybridizing 23S ribosomal RNA (rRNA) with *Pvu*II digests of replicating ctDNA. In agreement with the restriction map of Fig. 2, R-loops were observed on *Pvu* A fragments only. The region containing the three 23S cistrons is 4.7 ± 0.1 µm long ($n=14$) while the adjacent segments spanning 3′ and 5′ of

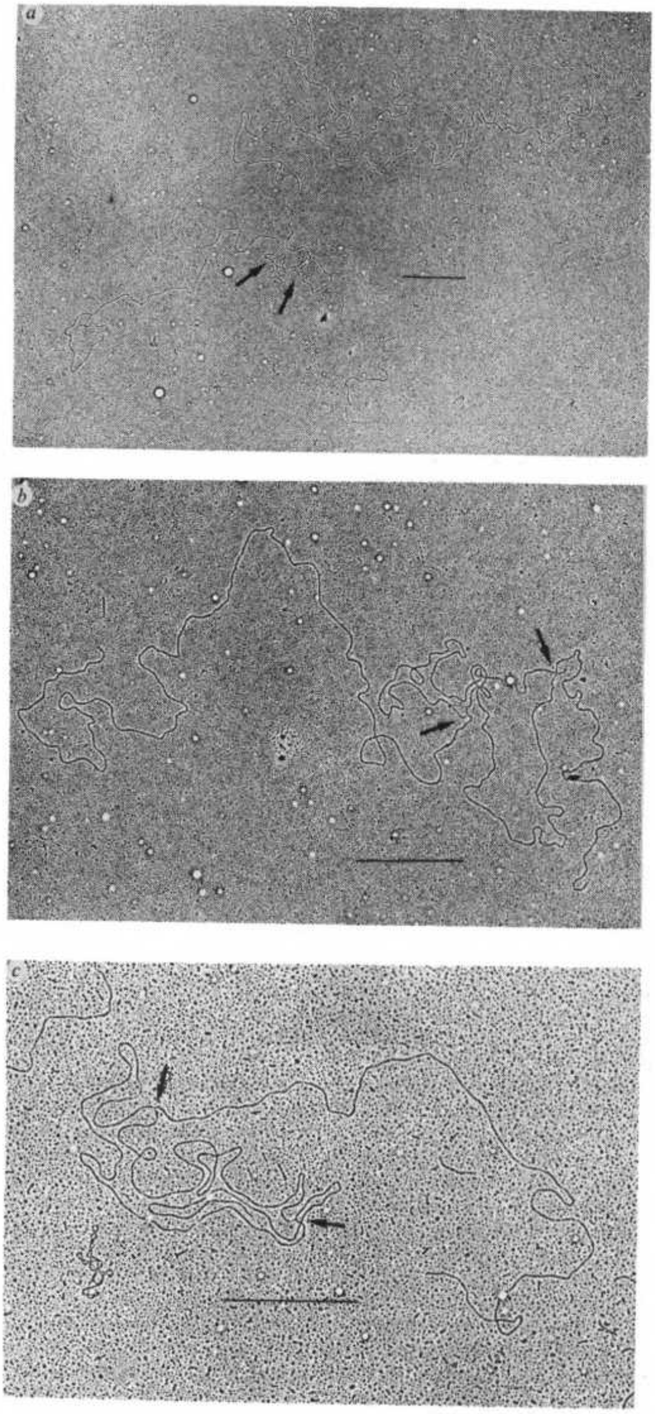

Fig. 1 Restriction fragments bearing replication loops. Synchronous cultures of *Euglena gracilis* Z (strain 1224–5/25 from Göttingen Algensammlung) were grown phototrophically on mineral medium[29] plus vitamins B_1 and B_{12} and aerated with air/CO_2 (95:5) in 20-l carboys at 27 °C. Cultures were synchronized by light–dark cycles (12 h/12 h; 5,000 lux) and were collected between 6 and 8 h after onset of the light phase at densities of $2\text{–}2.5 \times 10^5$ cells ml^{-1}. Chloroplasts were isolated by sucrose flotation according to ref. 3. Replicating DNA was isolated by CsCl/ethidium bromide gradient centrifugation[5]. After digestion with *Pvu*II (Boehringer) or *Xho*I (BRL), DNA was mounted for electron microscopy by the formamide technique[30], with pBR322 plasmid as internal standard. Grids were stained with uranyl acetate and rotary-shadowed with Pt/Pd (80:20). Calibrations of the electron microscope were made using a diffraction grating replica (2,160 lines mm^{-1}; Agar Aids). Arrows indicate the replication forks on fragment of ctDNA digested by *Pvu*II (*a*, *b*) or *Xho*I (*c*). The extent of replication is *a*, 3%; *b*, 13.5%; and *c*, 12.5% of the entire ctDNA molecule. In *a* and *b* one of the Cairns forks shows branch migration[31]. Scale bar, 1 μm.

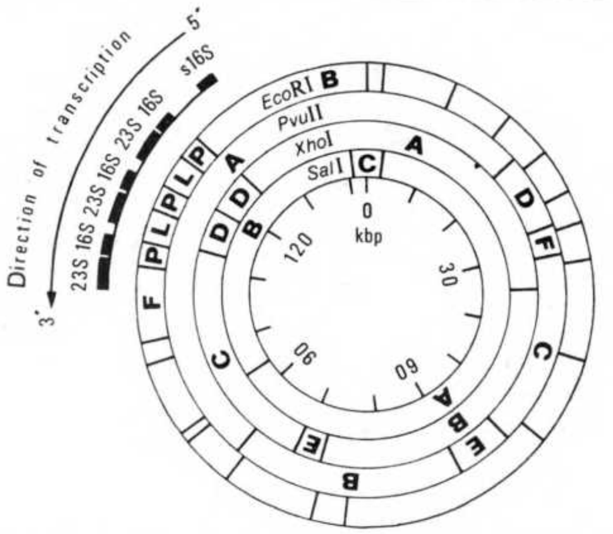

Fig. 2 Physical restriction map of *Euglena* ctDNA from Hallick[12]. s16S is the supplementary 16S rRNA gene[9].

these ribosomal genes are, respectively, 6.2 μm and 11.5 μm long. When *Pvu* A fragments simultaneously carrying R-loops and a replication loop were observed, the replication loops were found on the 11.5 μm-long side of the *Pvu* A fragments (13 molecules observed; Figs 3, 4). These results demonstrate that replication is initiated in a unique region of the ctDNA molecule 5′ to the ribosomal genes.

The two branches of the replication loops appear to be double-stranded except for a region of variable length on one of the branches at each of the replication forks, as already observed by Richards and Manning[5]. When replication covers the ribosomal region totally or partially, both branches of the replication bubble carry R-loops (Fig. 3*b*, *c*). This demonstrates that both ctDNA strands are replicated simultaneously in *Euglena*. In contrast, a large fraction of the H-strand of mitochondrial DNA is replicated unidirectionally before replication of the L-strand starts[11].

In Fig. 4, we have aligned 35 molecules bearing replication loops. The top of the histogram, assembled from the replication loops of *Pvu* A fragments (locus 0 in Fig. 4*a*) is located 11 kbp from the 5′ end of the first 23S cistron (taking 14 kbp for the length of the 23S region[12]), that is, about 5 kbp from the 5′ end of the supplementary 16S gene. The shape of the histogram is fairly symmetrical, suggesting that the replication is essentially bidirectional; however, the origin of replication thus determined is not necessarily located at the centre of the replication loops observed on individual molecules. One must assume that the migration rates of the two Cairns forks may differ widely from each other in some molecules, yielding almost unidirectional replication. In some molecules observed, the origin of replication determined by the histogram is not located in the replication loop. This cannot be due to experimental errors of measurement (see Fig. 4*b* for reproducibility of 23S cistrons positioning). Our results, however, do not exclude the possibility of two neighbouring replication origins as described for pea and maize[6]. Moreover, replication is initiated in a region demonstrated to be heterogeneous[13] (region *Bgl* Z) and to contain an inverted repeat of variable length[14]. Thus, it is possible that the variability observed in replication figures may result from the structural variability of this region.

Note for comparison that the replication origin is close to the ribosomal cistrons in various mitochondrial genomes (rat[15], mouse[16], man[17], *Xenopus*[18] and *Drosophila*[19]), and is associated with inverted repeated structures in several replicons (mitochondria[11], *Escherichia coli*[20], lambdoid coliphages[21], simian virus 40[22] and the 2 μm plasmid of yeast[23]). The mitochondrial genome of wild-type yeast cells apparently contains several putative origins of replication, one of them at least

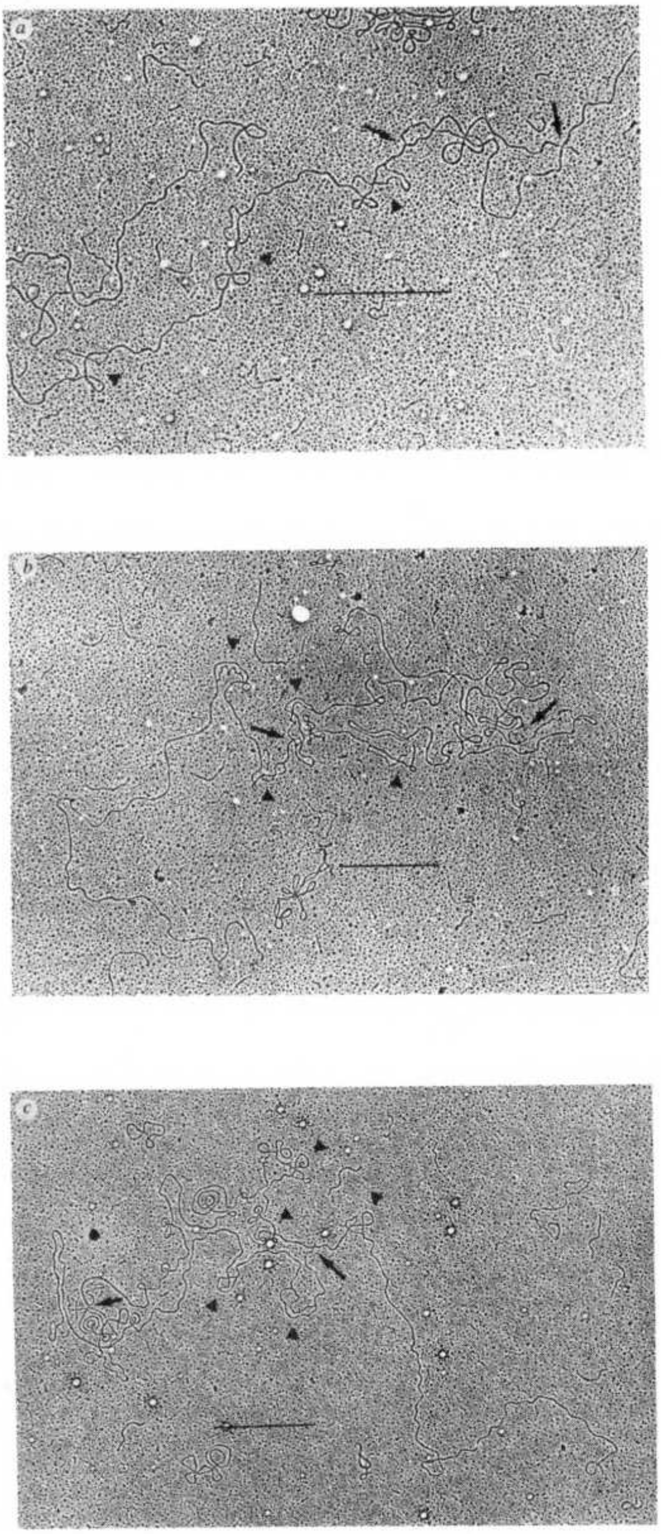

Fig. 3 *Pvu* A restriction fragments bearing simultaneously R-loops and a replication loop. ctDNA was prepared, digested and spread as described for Fig. 1. rRNA was phenol-extracted from SDS-lysed chloroplasts and 23S RNA was purified by 1.5% agarose gel electrophoresis, electroelution and alcohol precipitation. R-loops were formed according to Wellauer and Dawid[23] (incubation for 16 h at 45 °C). Arrows indicate R-loops. *a*, Replication concerns 5% of the total genome but not the ribosomal cistrons. A details of the ribosomal and replicated region is shown. *b*, Replication concerns 18% of the genome; the first 23S cistron has been replicated. *c*, 29% of the total genome and two 23S cistrons have been replicated. These molecules show branch migrations at one replication fork. Small circular molecules are pBR322 plasmid DNA. Scale bar, 1 μm.

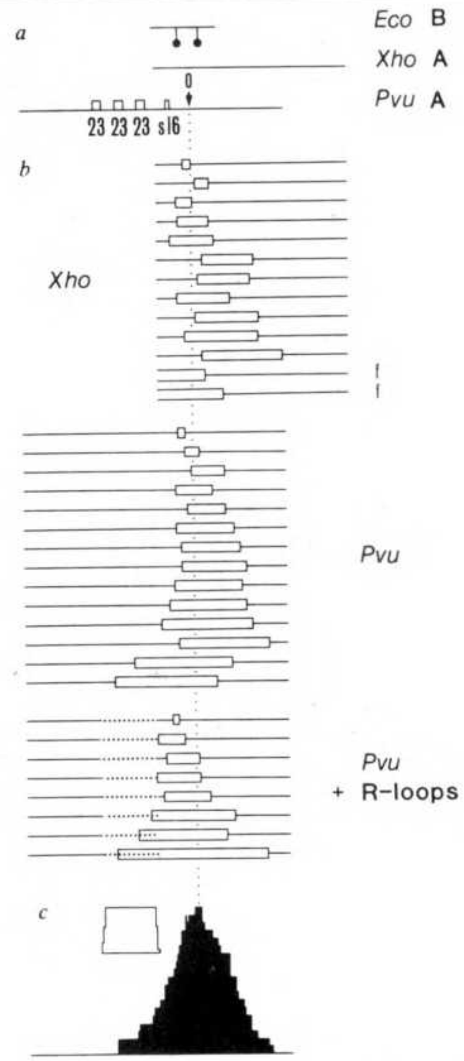

Fig. 4 Alignment of replication patterns with the physical restriction map. *a*, Relative positions of restriction fragments *Pvu* A, *Xho* A and *Eco* B from the physical map of Hallick[12] (Fig. 2). ● Represents the limits of the *Bgl* Z region as defined by Jenni *et al.*[13]. The positions of ribosomal 23S and supplementary 16S cistrons are indicated on the *Pvu* A fragment; 0 corresponds to the top of the histogram from *c*. *b*, Restriction fragments carrying replication loops. Restriction fragments were analysed by measuring the non-replicated portions and both branches of the replication loops of each individual restriction fragment. For all molecules observed, the two branches of the replication loops were identical in length (± 5%); individual restriction fragments had total lengths within ±7% of the average fragment length. Only replication loops larger than 0.5 μm were taken into account to avoid possible confusion with denaturation loops, which are generally rare and smaller than 400–500 bp (~0.15 μm). Open boxes represent the replication bubbles; dotted lines represent the region covered by 23S R-loops. In each group molecules are arranged according to increasing extent of replication. f, Forked molecules. *c*, Histogram of cumulated *Pvu* A fragments from *b*. The open histogram indicates the position of the 23S ribosomal region observed on *Pvu* fragments.

being carried by each of the segments excized and repeated in spontaneous petites mutants[24]. In an analogous way, ribosomal DNA amplification in *Tetrahymena* seems to proceed after excision of a rDNA segment from the micronucleus chromosomal DNA during conjugation, followed by extensive replication of extrachromosomal rDNA molecules due to the presence of an origin of replication located on the excized segments[25]. Similarly, the tandem arrangement of the ribosomal cistrons in *Euglena*, together with their close proximity to the replication origin, could explain the relative amplification of these ribosomal cistrons described during mutagenesis[26] or suggested during the cell cycle[27,28].

This work was supported by CNRS grant ATP 8068. EM observations were performed at the Electron Microscopy Center of the Université Lyon-I.

Impaired nuclear transport of a human variant tRNA$_i^{Met}$

Michael Zasloff*‡, Martin Rosenberg† & Tomas Santos*‡

* Genetics and Biochemistry Branch, National Institute of Arthritis, Diabetes, Digestive and Kidney Diseases, and † Laboratory of Biochemistry, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

Recently, a human variant tRNA$_i^{Met}$ (initiator tRNA^{Met}) gene has been cloned from a recombinant library of fetal liver DNA[1]. This gene contains a G to T transversion within the highly conserved TCGA sequence in loop 4 ('Tψ loop'), a sequence position occupied exclusively by a purine (usually G) in almost 200 prokaryotic and eukaryotic tRNAs[2]. Recent studies with the cloned gene, both *in vitro*[3] and when expressed in an intact cell on a simian virus 40 viral vector[4], have shown that one functional consequence of this base substitution is a reduction in the rate of processing of the primary transcript of the gene. This reaction involves sequential excision of 5′- and 3′-terminal sequences[3]. Here we show that following microinjection of the variant tRNA$_i^{Met}$ gene into the germinal vesicle of the intact *Xenopus laevis* oocyte, the primary transcript is slowly but accurately processed to a mature variant tRNA$_i^{Met}$ species which remains trapped within the oocyte nucleus, its escape apparently being prevented by the nuclear membrane. This is the first evidence that the transport of a tRNA molecule can be blocked by a point mutation. The results suggest that a selective tRNA nuclear transport mechanism exists in the eukaryotic cell and identify a critical role for the highly conserved Tψ loop in this process.

The *X. laevis* oocyte has been shown to accurately transcribe and process several homologous and heterologous tRNA genes[5–9] and provides a system for studying the intracellular distribution of intermediates in tRNA biosynthesis. After microinjection of either a cloned tRNA gene or a purified transcript, the oocyte can be manually dissected and the RNA species within the nucleus and cytoplasm analysed separately[8,9]. The intracellular distribution of tRNA intermediates is preserved during manual dissection, in contrast to the 'leakiness' of somatic nuclei with respect to these species[10], when isolated by standard aqueous fractionation.

The DNA sequences of the two human tRNA$_i^{Met}$ genes used in this study are co-linear with that of mature tRNA$_i^{Met}$ and neither contains an intervening sequence[1]; gene 1 is a variant differing from the common vertebrate tRNA$_i^{Met}$ sequence by a G to T transversion at position 56 in the DNA sequence (corresponding to position 57 in the standard tRNA numbering scheme[2]), and gene 2 contains the common vertebrate sequence. The 5′ and 3′ flanking sequences of the two genes share only limited homology, with the corresponding primary transcripts of each gene differing in both the sequence and length of the 5′ leader and 3′ trailer[3]. Plasmids phH1E (gene 1) and phH2D (gene 2), described in detail elsewhere[1], each contain a human chromosomal fragment bearing a single tRNA gene.

The two plasmids were microinjected separately into the germinal vesicle of stage 6 *X. laevis* oocytes. Five hours after injection of the gene plus [α-^{32}P]GTP, RNA was extracted and

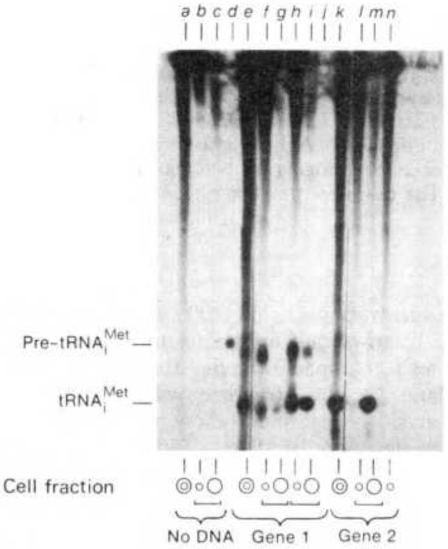

Fig. 1 Intracellular distribution of ^{32}P-labelled RNA species in *X. laevis* oocytes after microinjection of human tRNA$_i^{Met}$ genes. Ovaries were collected from gravid *X. laevis* females and microinjected as described elsewhere[5]; ~20 nl of solution containing 10 ng of plasmid were injected per nucleus. Plasmids phHIE (gene 1) and phH2D (gene 2) have been described in detail elsewhere[1]. Plasmids were isolated by acid–phenol extraction[18] followed by gel filtration over Sepharose 4B. After injection of the plasmid, 50 nl of [α-^{32}P]GTP (10 mCi ml^{-1}; SA 760 Ci mmol^{-1}, NEN) were injected in a separate step into either the vegetal (white) pole or the equator. Oocytes were maintained at 21 °C for 5 h. RNA was extracted from either the whole oocyte or the separated germinal vesicle and cytoplasm, manually dissected as described by Melton *et al.*[9]. RNA was electrophoresed on a 10% acrylamide gel containing 7 M urea and autoradiographed for 12 h as described[3]. No exogenous DNA injected: *a*, whole oocyte; *b*, germinal vesicle; *c*, cytoplasm. phHIE (gene 1) injected: *e*, whole oocyte; *f*, *h*, germinal vesicles; and *g*, *i*, corresponding cytoplasmic fractions. phH2D (gene 2) injected: *k*, whole oocyte; *l*, *n*, germinal vesicle; and *m*, corresponding cytoplasm (cytoplasmic fraction associated with the vesicle in lane *n* is not presented). Lanes *d* and *j*, ^{32}P-labelled primary transcripts of gene 1 and gene 2, respectively, synthesized *in vitro*[3] (see Fig. 3 legend), were included as size markers.

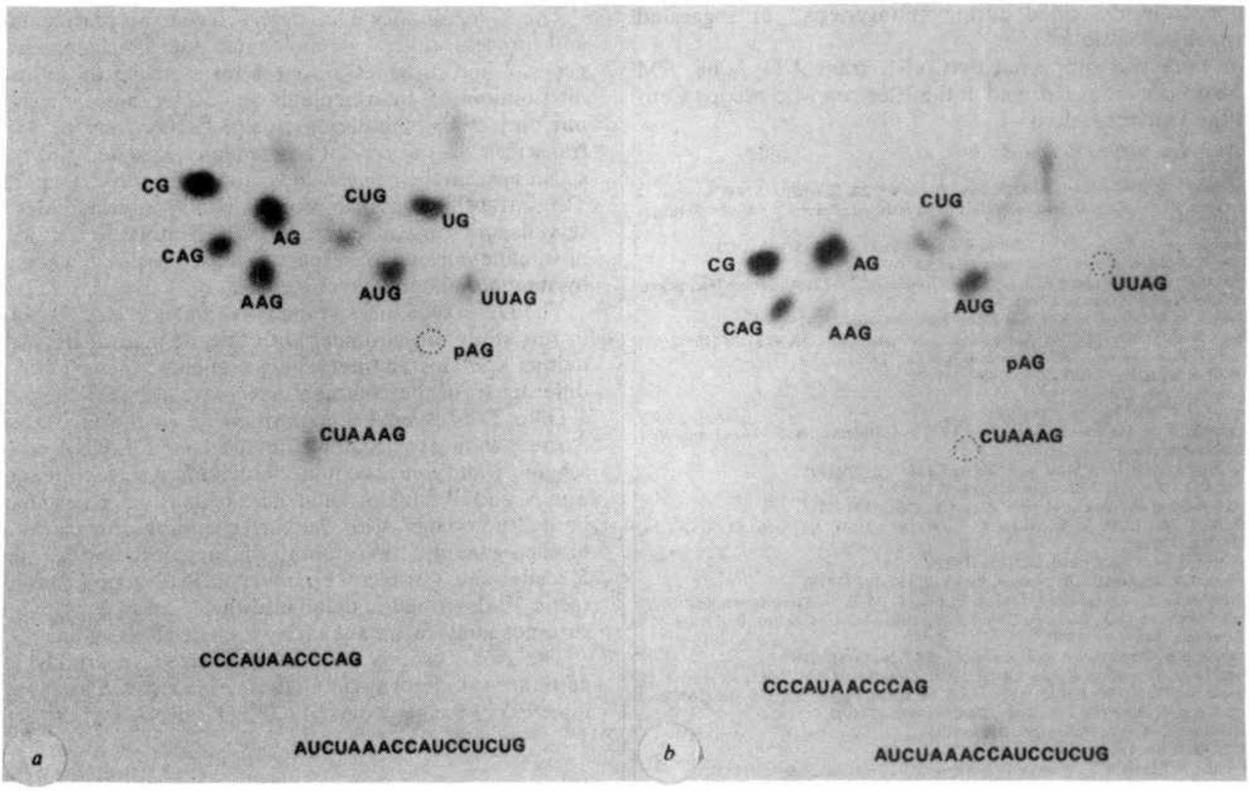

Fig. 2 RNase T_1 oligonucleotide fingerprint of gene 1 pre-$tRNA_i^{Met}$ and intranuclear $tRNA_i^{Met}$. RNA species were extracted from the gel shown in Fig. 1*f* and fingerprinted by classical techniques as described elsewhere[3]. Expected positions of certain oligonucleotides not observed in each fingerprint are indicated by dotted circles. *a*, Pre-$tRNA_i^{Met}$ transcribed from gene 1. The long oligonucleotide characteristic of the variant, AUCUAAACCAUCCUCUG, results from the elimination of an AUCG in loop 4 due to base substitution of G for U. The oligonoucleotide CUAAAG can also be seen, bridging the 3′ end of the mature sequence and 3′ trailer. UUAG arises from position −2 in the DNA sequence, bridging the two nucleotides of the 5′ leader and two nucleotides from the start of the mature sequence. *b*, Intranuclear $tRNA_i^{Met}$. The characteristic long oligonucleotide is present, demonstrating the presence of the mutation within the loop 4 region. The 3′ bridging sequence, CUAAAG, is absent and the mature 5′ end, pAG, is present.

analysed by electrophoresis in 10% acrylamide gels in 7 M urea. Figure 1 shows that injection of gene 2 resulted in the synthesis of an RNA species having the mobility expected for $tRNA_i^{Met}$ (lane *k*); the structure was confirmed by RNA sequence analysis as described below. On injection of gene 1, two major species were produced (Fig. 1*e*); the slower is the precursor of the variant tRNA while the faster, major species, is mature variant $tRNA_i^{Met}$.

To determine the intracellular distribution of the transcripts of the normal and mutant $tRNA_i^{Met}$ genes, the gene plus [α-^{32}P]GTP were injected into the germinal vesicle of an intact oocyte and kept at 21 °C for 5 h; the oocyte was then manually dissected and RNA species extracted from the separated nucleus and cytoplasm. The $tRNA_i^{Met}$ species synthesized from the normal gene was found principally in the cytoplasmic compartment (Fig. 1*m*) with about 1% of the total newly synthesized $tRNA_i^{Met}$ remaining in the germinal vesicle (Fig. 1*l*, *n*). As the volume of the germinal vesicle is about 10% that of the oocyte[11], the intranuclear concentration is lower than would be expected from free diffusion of the species between nucleus and cytoplasm and suggests that the $tRNA_i^{Met}$ partitions preferentially in the cytoplasm.

The intracellular distribution of the RNA species transcribed from the mutant gene differed strikingly from that observed for normal $tRNA_i^{Met}$. As seen in the representative pair of oocyte dissections, the germinal vesicle contained, in addition to the precursor species, between 80% (Fig. 1, lanes *f*, *g*) and 60% (Fig. 1*h*, *i*) of the newly synthesized variant tRNA. Because tearing of the germinal vesicle membrane leads to leakage of the intranuclear tRNA species, as we show below, we cannot exclude the possibility that the cytoplasmic component was solely an artefact of isolation. Note, however, that the relative proportion of the tRNA species present in each compartment did not change significantly with time up to 18 h.

The putative variant tRNA precursor, and the nuclear and cytoplasmic tRNA species were isolated and analysed by classical two-dimensional T_1 RNase oligonucleotide fingerprinting[12]. The fingerprints generated were compared with previous analyses of the *in vitro* transcripts of this gene[3]. The fingerprint of the slowly migrating species (Fig. 2*a*) is characteristic of the precursor, while that of the intranuclear tRNA (Fig. 2*b*) is characteristic of the mature variant $tRNA_i^{Met}$. Fingerprint analysis of the tRNA synthesized in the presence of [α-^{32}P]CTP revealed an oligonucleotide with location and composition consistent with the mature 3′-terminal oligonucleotide $CUACCA^{OH}$, demonstrating terminal CCA addition on the accurately processed terminus (data not shown). A fingerprint of the variant tRNA recovered from the cytoplasm appeared identical to that of the intranuclear species (data not shown).

To determine whether the processing and transport behaviour of the mutant tRNA could be demonstrated with purified RNA species, ^{32}P-labelled primary transcripts of each gene synthesized *in vitro*[3] were injected separately into individual oocytes. After 5 h incubation, the RNA was extracted from either the whole oocyte or from the germinal vesicle and cytoplasm after manual dissection. Injection of the purified primary transcripts resulted in a similar appearance and intracellular distribution of species observed during active transcription in the oocyte. Thus, the primary gene 2 transcript was fully converted to $tRNA_i^{Met}$ (Fig. 3*k*) 5 h after nuclear injection. The processing nucleases appear to be intranuclear, because injection of the same quantity of precursor into the cytoplasm resulted in less efficient conversion (Fig. 3*l*). Analysis of the distribution of the $tRNA_i^{Met}$ species revealed that virtually

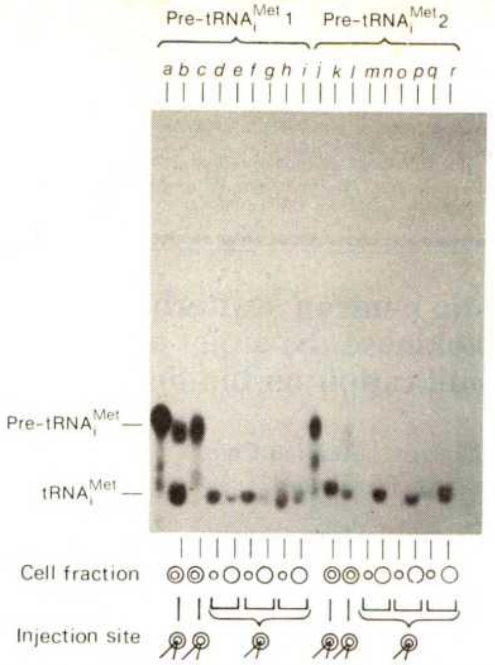

Fig. 3 Intracellular processing and distribution of ^{32}P-labelled tRNA$_i^{Met}$ primary transcripts after microinjection of the purified RNA into *X. laevis* oocytes. The primary transcripts of gene 1 and gene 2 were synthesized *in vitro* using a partially purified KB cell postnuclear fraction as described previously[3], and have been shown to be identical in sequence to the species synthesized in the *X. laevis* oocyte extract[3]. The gene 1 primary transcript, 90 nucleotides long, contains a 3-base 5′ leader and a 13-base 3′ trailer, while the 89-base gene 2 transcript contains an 8-base leader and trailer[3]. The RNA species were purified from the transcription reactions by phenol extraction, concentrated by ethanol precipitation, and then resuspended in a small volume of 88 mM NaCl, 20 mM Tris-HCl *p*H 8.0. RNA solutions were injected into oocyte nuclei, as described in Fig. 1 legend, or into the cytoplasmic pole. Following incubation at 21 °C for 5 h, RNA was extracted from either whole oocytes or nuclear and cytoplasmic fractions, obtained as described in Fig. 1 legend. *a*, Primary transcript of gene 1 synthesized *in vitro*. *b*, Whole oocyte, following injection into the germinal vesicle of the amount of ^{32}P-RNA shown in *a*. *c*, Whole oocyte, following injection into the cytoplasm. *d, f, h*, Germinal vesicles; *e, g, i*, corresponding cytoplasmic fractions following germinal vesicle injections. Lanes *j–r* show corresponding data obtained after injection of the primary transcript of gene 2.

no tRNA$_i^{Met}$ remained within the nucleus; it was localized within the cytoplasm, as shown in three sets of single oocyte dissections (Fig. 3*m*/*n*, *o*/*p* and *q*/*r*).

The primary transcript of gene 1 was processed to a tRNA species more slowly than that of gene 2, and the variant tRNA$_i^{Met}$ was inefficiently transported from the oocyte nucleus. About 50% of the primary transcript of gene 1 was processed to a tRNA by 5 h after microinjection into the germinal vesicle (Fig. 3*b*). We estimate that the rate of processing of this transcript is about 5% of that observed for the gene 2 species, since 50% conversion of the gene 2 transcript occurred within about 15 min after microinjection (data not shown). As demonstrated in three individual oocyte dissections, between 90% (Fig. 3*d*/*e* and *f*/*g*) and 60% (Fig. 3*h*/*i*) of the processed mutant tRNA$_i^{Met}$ remained within the germinal vesicle 5 h after intranuclear injection of the gene 1 transcript. The gene 1 primary transcript was not significantly processed after injection into the cytoplasm of the oocyte (Fig. 3*c*), which demonstrates that the primary transcript of the variant gene cannot efficiently enter the nucleus from the cytoplasmic compartment during this period.

To determine the mechanism by which the tRNA$_i^{Met}$ remains sequestered within the nucleus of the oocyte, we asked whether this mutant tRNA was limited from free diffusion by the nuclear membrane, by physical attachment to a cellular component such as the membrane itself or the intranuclear matrix, or due to its association with a large soluble marcomolecule which might itself be limited from leaving the germinal vesicle. Five hours after injection of gene 1 and [α-^{32}P]GTP, the germinal vesicles were manually isolated and placed in a small volume of J buffer[13] (70 mM NH_4Cl, 7 mM $MgCl_2$, 0.1 mM EDTA, 2.5 mM dithiothreitol, 10 mM HEPES *p*H 7.4, 10% glycerol) or the same buffer containing 1% Triton X-100. [In the presence of this non-ionic detergent the nuclear membrane is disrupted without apparent effect on the basic overall structural integrity of the intranuclear matrix, and the surrounding pore lamina system or 'envelope'[14]. Figure 4 (inset) shows a low power magnification of a germinal vesicle suspended for 30 min at 21 °C in J buffer containing Triton X-100. No appreciable difference in gross morphology was observed between the germinal vesicle thus treated and one suspended in J buffer alone for this period of time.] After incubation of the isolated germinal vesicle in J buffer, the labelled RNA species remained within the nucleus (Fig. 4*c*) with little RNA found in the surrounding buffer (lane *d*). In contrast, treatment of the germinal vesicle with the solution containing Triton X-100 resulted in the almost complete release of the RNA species from the nucleus (Fig. 4*e*) to the surrounding solution (lane *f*).

Thus, treatment of the germinal vesicle in conditions which lead to dissolution of the nuclear membrane without gross physical disruption of the nucleus, results in leakage of the

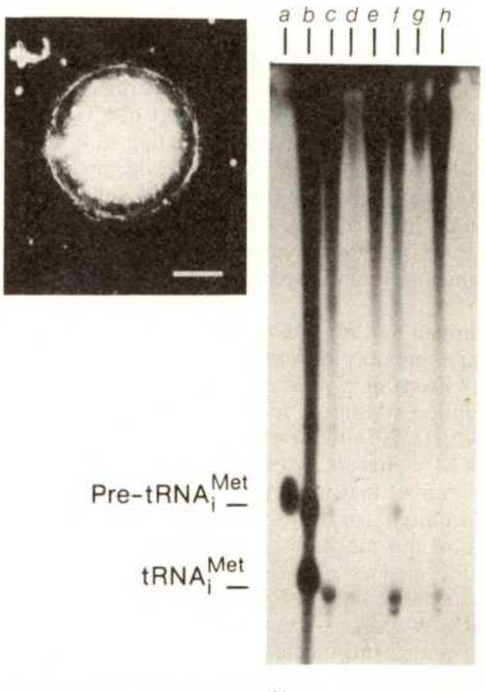

Fig. 4 Intranuclear variant tRNA$_i^{Met}$ is trapped in the germinal vesicle by the nuclear membrane. ^{32}P-RNA was synthesized in oocytes after injection of phHIE (gene 1) as described in Fig. 1 legend. *a*, Gene 1 primary transcript synthesized *in vitro*. *b*, RNA extracted from whole oocyte. Germinal vesicles were isolated as described in Fig. 1 legend and suspended in 300 µl of either J buffer[13] or J buffer containing 1% Triton X-100, and maintained at 21 °C for 30 min, at which time the RNA species present in both nucleus and surrounding buffer were analysed. Germinal vesicle suspended in J buffer alone: *c*, germinal vesicle; *d*, surrounding fluid. Germinal vesicle suspended in J buffer plus Triton X-100: *e*, germinal vesicle; *f*, surrounding fluid. One germinal vesicle was placed in J buffer and the nuclear membrane manually separated from the nucleoplasm: g, RNA associated with nuclear membrane; *h*, intranuclear contents. Inset, *X. laevis* germinal vesicle after incubation at 21 °C for 30 min in J buffer containing 1% Triton X-100. No change in gross morphology of the germinal vesicle was observed after detergent treatment. Note the nuclear envelope, nucleoplasmic gel, and numerous amplified nucleoli. (Nomarski phase optics; scale bar, 0.1 mm.)

variant tRNA$_i^{Met}$. To determine whether the RNA species is released as a result of the membrane acting as a diffusion barrier or as a result of previous attachment of the tRNA species to the membrane, a germinal vesicle, previously injected with gene 1 and [α-^{32}P]GTP, was placed in J buffer (not containing Triton X-100) and manually stripped of its enclosing nuclear envelope as described elsewhere[13]. When the contents of the nucleus were separated from the membrane, the variant tRNA$_i^{Met}$ partitioned with the nucleoplasmic contents (Fig. 4*h*) rather than the membrane (lane *g*).

Velocity sedimentation analysis of the intranuclear contents of the manually stripped germinal vesicle revealed that the intranuclear tRNA$_i^{Met}$ species has a mobility of ~4S (data not shown). This experiment demonstrates that the species is not associated within the nucleus in a large macromolecular complex (such as the 42S particle[15]) and, even in the absence of detergent treatment, is not bound tightly to such components as the nuclear gel, the intranuclear scaffold, or chromatin (nuclear and nucleolar).

We have demonstrated here that a human variant tRNA$_i^{Met}$ containing a base substitution within the highly conserved loop 4 region is transported inefficiently from the oocyte nucleus. Although only tRNA species having mature 5′ and 3′ termini can leave the nucleus, as noted here and in an earlier study[9], our data reveal that accurate nucleolytic processing of a tRNA molecule will not guarantee nuclear escape. In addition, the trapping of the variant tRNA$_i^{Met}$ within the oocyte nucleus demonstrates that the nuclear membrane can restrict the diffusion of a mature tRNA species and provides evidence for the existence of a tRNA transport mechanism. The behaviour of the variant tRNA$_i^{Met}$ strongly suggests that the highly conserved UCGA sequence within the loop 4 region of eukaryotic tRNA has a role in the overall transport of a tRNA molecule across the nuclear membrane. Our finding that the variant is processed slowly in addition to being transported inefficiently suggests that the mechanisms of processing and transport might be functionally inter-related. Alternatively, both processing and transport may operate by entirely independent mechanisms, each recognizing common sequences (or structure) in the tRNA molecule.

Is this human variant tRNA$_i^{Met}$ a 'pseudogene' in the sense of an inactive member of a multigene family, or might it have a function? From *in vitro* studies of several RNA polymerase III transcription systems it appears that feedback inhibition by either tRNA (U. Affolter and M. Z., unpublished observations) or 5S rRNA[16,17] occurs, presumably by the binding of RNA with a component that is present in rate-limiting amounts and which is required for transcription initiation. It is unclear, however, how this mechanism might operate in the intact cell, as tRNA once processed is rapidly excluded from the nucleus, with no detectable back transport of mature tRNA from the cytoplasm[11]. We suggest that this human variant tRNA$_i^{Met}$ (either as a mature intranuclear species, or as a slowly processed precursor) might provide the intranuclear transcription aparatus with a means of sensing the output of the multigene tRNA$_i^{Met}$ family, perhaps by the mechanism suggested by the *in vitro* studies described.

We thank Joanne Nickol and William Bonner for technical advice during the initial phases of our oocyte studies, and Mrs Mary Keffer for help in preparation of the manuscript.

The dynamical behaviour of proteins and its significance to protein function has become the subject of considerable experimental and theoretical investigation[1,2]. The existence of atomic motion about mean positions has been well established by the temperature dependence of X-ray diffraction[3] and it has long been recognized that considerable internal mobility is required in proteins to account for hydrogen exchange measurements[4]. However, only limited experimental information, mainly obtained by optical methods[5], is available on the frequencies associated with these fluctuations. Inelastic neutron scattering is a technique capable of yielding dynamical information about a system over a wide frequency range[6,7]. Recent advances in neutron spectrometers[8] and in the theoretical understanding of the dynamics of biological macromolecules have now made it both feasible and desirable to exploit this technique in the field of biophysics. To demonstrate the potential of the method, we report here data on the frequency distribution in solution of the enzyme hexokinase and its modification brought about on binding of its substrate glucose. The results lend support to the view that ligation induces a stiffening of the enzyme structure.

Inelastic neutron scattering arises when incident neutrons gain or lose energy as a result of interaction with the internal modes of motion of a sample. Techniques to measure these energy changes are routinely used to study the dynamics of solids and liquids[6]. In the case of organic molecules the signal is dominated by the incoherent scattering by the hydrogen nuclei and can be related to the frequency spectrum of the sample[7]. However, the application of this technique to proteins in solution is hampered by the necessarily low protein concentration (at best a few per cent) which means that all measured spectra are dominated by the scattering by the buffer. Use of buffers made from D_2O minimizes this background, but despite this, several previous attempts to measure the inelastic spectra of proteins in solution have suffered from insufficient statistical accuracy. This has been overcome by the time focusing time-of-flight spectrometer IN6[8] (see Fig. 1 legend) which has recently become available at the Institut Laue-Langevin, and enables measurements to be made with good counting statistics. Inelastic neutron scattering data on polycrystalline lysozyme have been reported previously[9].

We have chosen yeast hexokinase (molecular weight 50,000) for this investigation for the following reasons. Its structure is known from X-ray crystallography[10] and consists of two large domains with a deep cleft between them. A crystallographic study of an isozyme of hexokinase complexed with glucose has shown that in the complex the two domains have rotated so as

0028-0836/82/440084—03$01.00

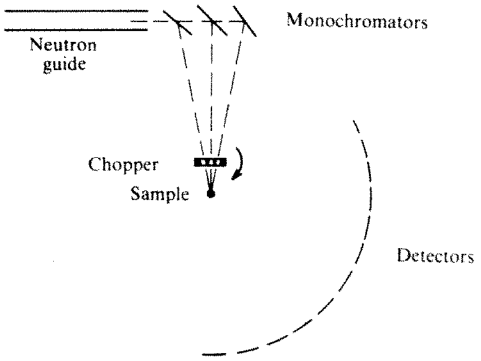

Fig. 1 Schematic diagram of time-focusing spectrometer IN6 viewed from above. Neutrons arriving through a guide tube ($3 \times 20\ \mathrm{cm}^2$) are monochromatized by a series of three pyrolytic graphite crystals with slightly different orientations. Each crystal reflects a different wavelength but all beams are focused on the sample. Pulses of neutrons are produced by a chopper which rotates about a vertical axis and is placed 40 cm before the sample. The chopper is designed so that the wavelength differences between the sub-beams are compensated by different times of chopping. In this way all elastically scattered neutrons arrive at the detector at the same time (time focusing). The instrument thus combines a high flux with a reasonable resolution (~ 0.15 meV or $1.2\ \mathrm{cm}^{-1}$ at the elastic peak). In the direction perpendicular to the diagram the neutron guide tube is 20 cm in height and a geometrical focusing of the beam in that direction is achieved by curved composite monochromators. The inelastically scattered spectrum is analysed by measuring the time of flight from the sample to a bank of detectors 247 cm away. The detectors were grouped to give 24 time-of-flight spectra corresponding to scattering angles between 10 and 115°. Each time-of-flight spectrum had 512 channels. Incident neutrons of wavelength 4.1 Å (4.87 meV) were used.

to trap the glucose in the cleft[11,12]. That this conformational change on binding of glucose actually occurs in solution has been confirmed by measuring the corresponding change in the radius of gyration using small-angle X-ray scattering[13]. The interest in making inelastic neutron scattering measurements on this system follows from the speculation that the binding of glucose in the cleft and resultant conformational change may modify the vibrational spectrum of hexokinase. In particular, relative motion of the two domains may be hindered on ligation. Furthermore, it has been argued that a change in the frequency spectrum of an enzyme on ligation may be significant in the thermodynamics of enzymatic reactions[14].

The experimental strategy was to collect data successively from the buffer, the hexokinase solution and the hexokinase saturated with glucose, all at 15 °C and in the same quartz cell. Figure 2 shows corrected and scaled spectra obtained by summing counts in the range of scattering angle between 84° and 110°. The spectra of the hexokinase solution and the buffer appear similar but the statistical accuracy is sufficiently high to show that the enzyme spectrum is significantly different in form from the unsubtracted spectrum. The signal from the protein is about 15% of the total. In subtracting the buffer a factor was introduced to take into account the lower buffer content of the protein solution. We verified that variation of this scaling factor by ±5% (a wider margin of error than the true error) did not significantly affect the form of the protein spectrum (in particular the peak around $50\ \mathrm{cm}^{-1}$). Thus, we believe that curves *c* and *d* in Fig. 2 are an accurate representation of the inelastic neutron spectra of hexokinase and hexokinase bound with glucose. Spectra were simultaneously measured at several scattering angles between 10° and 115°, and the angular dependence of the spectra can be summarized as follows. The intensity of the elastic peak of both the ligated and unligated spectra decrease roughly as $\exp(-0.89Q^2)$. The two main features of the inelastic spectrum—the peaks around 50 and $300\ \mathrm{cm}^{-1}$—behave differently. The former increases in intensity with angle while the latter maintains the same intensity and is hardly distinguishable as a distinct peak at a scattering angle of 97°. This different behaviour with angle of high and low frequency

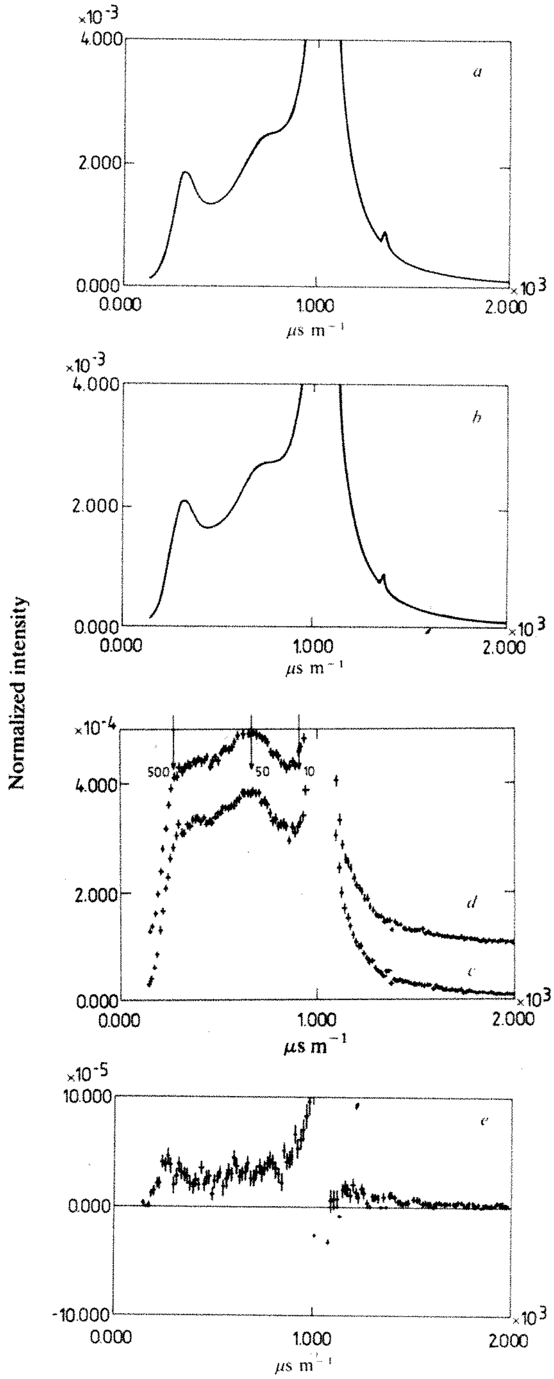

Fig 2 Time-of-flight spectra measured at a mean angle of 97° of buffer (*a*) and hexokinase solution (*b*). The ordinates have been scaled by the elastic peaks measured with a vanadium sample. The abscissa is in time-of-flight (TOF) units ($\mu\mathrm{s\ m}^{-1}$). Neutron energies are related to TOF by $E\ (\mathrm{cm}^{-1}) = 42.2 \times 10^6/(\mathrm{TOF})^2$. The sharp peak on the energy loss side of both spectra is due to parasitic Bragg scattering from an aluminium window. Subtraction of the buffer (and quartz cell) scattering gives the corrected spectra of hexokinase (*c*) and hexokinase bound with glucose (*d*) (curve shifted by 10^{-4}). Energy transfers of 10, 50 and $500\ \mathrm{cm}^{-1}$ are indicated by arrows. The difference spectrum obtained by subtracting *c* from *d* is shown in *e*. The error bars are derived from the counting statistics and show 1 s.d. from the nominal value. Hexokinase (Sigma lot 120F-8080) in crystalline suspension was redissolved in D_2O buffer containing 20 mM Tris, 0.1 M NaCl, 0.1 mM dithiothreitol, 0.1 mM sodium azide at $p\mathrm{D}(=p\mathrm{H})$ 8.5 and dialysed exhaustively against the same buffer. 0.8 ml of solution (previously concentrated to $45\ \mathrm{mg\ ml}^{-1}$) was then centrifuged at 16,000 r.p.m. for 5 min before being placed in a 1.5 mm thick quartz cell. The cell was set at 45° to the incident beam in the time-of-flight spectrometer and maintained at 15 °C. The sample chamber was maintained at a slight over pressure of helium throughout the experiment to avoid parasitic air scattering. To saturate the protein with its substrate, 1.8 mg of glucose per ml of solution was added, the glucose being in 50% (by weight) solution in the same D_2O buffer. The unexchanged protons of glucose increase the number of protons in the solution by about 3%. Spectra were accumulated for about 36 h each.

modes is consistent with the expected scattering by harmonic oscillators[7].

The dynamical modes of a protein should cover a wide range of different characteristic energies[2,5]. Some will be very similar to those found in small molecules, for example C—C bending and stretching modes and rotation of methyl groups. Characteristic energies for such local modes will be in the range 100–2,000 cm^{-1}. Others are collective modes specific to the secondary structure of proteins, for example longitudinal acoustic modes of helices with energies in the range 25–200 cm^{-1}. At still lower energies (1–50 cm^{-1}) 'breathing' modes as found in globular elastic bodies should occur, although the nature of these may be significantly modified by solvent damping[5]. Some of these low frequency modes may be directly linked with protein function, for example, the postulated hinge-bending mode in enzymes having a substrate binding cleft[15]. The inelastic spectra that we have measured extend up to more than 500 cm^{-1}, confirming the expected broad frequency spread of protein motions.

There are small but distinct differences between the spectra given by the enzyme with and without substrate bound (see Fig. 2*e*). First, there is an overall reduction of 5–10% in the intensity of inelastic scattering on glucose binding. This difference could be due *a priori* to a reduced number of protons in ligated hexokinase (resulting from a higher degree of exchange) or to a genuine modification of the enzyme dynamics. The first hypothesis is unlikely as the number of exchangeable protons is relatively small (20% of all protons) and is likely to decrease rather than increase with the tightening associated with substrate binding. Furthermore, neither the intensity nor the width of the elastic peak changes on ligation, suggesting that the total number of protons is unaltered. Thus, we conclude that there is a real modification of the dynamics of hexokinase on binding glucose. That the difference spectrum is positive suggests that the ligated enzyme has fewer and/or smaller amplitude vibrational modes, in accordance with the view that ligation induces a stiffening of the enzyme structure.

Second, Fig. 2*e* clearly shows that the shape of the difference profile differs from that of the total inelastic scattering by hexokinase. Thus, while ligation appears to affect both local and collective modes, different frequencies are affected to different extents. In particular, the low frequency modes ($<40\ \mathrm{cm}^{-1}$) are more markedly affected, as was also found to be the case on binding an inhibitor to lysozyme[9]. The hinge-bending mode of lysozyme has been calculated[15] to be between 5 and 15 cm^{-1}, and although no analogous calculations have been done for hexokinase, it is possible that the peak in the difference profile at 30 cm^{-1} corresponds to the disappearance of such a mode on closing of the cleft around the glucose substrate.

Intramolecular vibrational modes contribute to the enthalpy and entropy of a protein and it has been proposed that changes in the vibrational spectrum may be important in the thermodynamics of protein reactions[14]. Our results suggest that there is a reduction in the vibrational enthalpy of hexokinase on glucose binding. However, it has been shown recently that there is practically no overall change of enthalpy on binding of glucose[16]. This is not inconsistent with our finding, as a reduction in the enthalpy of the vibrational modes could be compensating for the burying of a charged group. Indeed, we note that such a group (Asp 189) is reported to be removed from contact with the solvent as a result of the conformational change[13]. In future experiments we aim to extract from the variation with angle of the inelastic scattering spectra the frequency distribution of vibrational modes of the sample[7]. This would allow estimation of the change in the vibrational contributions to the entropy and enthalpy on ligation.

In this exploratory application of inelastic neutron scattering, we have established that it is now feasible to use measurements of the frequency spectrum of proteins in solution to characterize the change in dynamical state associated with binding a substrate molecule. Clearly, further experiments of this kind will be needed to confirm the magnitude and significance of the observed changes. Several theoretical studies of protein fluctuations have been made by molecular dynamics simulations[2,15,17,18] and normal mode analysis[19], from which it is possible to predict inelastic neutron spectra. A more detailed interpretation of the inelastic neutron scattering spectrum of hexokinase would require careful comparison with the results of such calculations, although this is not yet practicable for such a large protein. Alternatively, one can envisage the use of selective labelling (for example, protonation of certain residues in an otherwise fully deuterated protein) to aid in assignment of particular modes. Thus, our results demonstrate the potential of inelastic neutron scattering for investigating the dynamic aspects of protein function and testing the theoretical understanding of protein dynamics.

Errata

In the letter 'Pluripotent embryonic stem cell lines can be derived from t^{w5}/t^{w5} blastocysts' by T. Magnuson *et al.*, *Nature* **298**, 750–753 (1982), in Fig. 2 the lowest bands on the gels should be labelled 17 (kilobases). In line 3 of Fig. 2 legend $129(t^0/t^{w5})$ is incorrect and should read $129(t^0/t^{w12})$.

In the letter 'Potent new inhibitors of human renin' by M. Szelke *et al.*, *Nature* **299**, 555–557 (1982), structure 4 in Table 1 erroneously contains the superscript R over the Phe-Phe peptide bond.

Corrigenda

In the letter 'Direct imaging of travelling Rayleigh waves by stroboscopic X-ray topography' by R. W. Whatmore *et al.*, *Nature* **299**, 44–46 (1982), the references to 'half-wavelength' or '$\pi/2$' in Fig. 4 legend and in the relevant discussion in the text should read 'one wavelength' or 'π'.

In the News and Views article 'Monoclonal antibodies to human malignant melanoma' by R. A. Reisfeld, *Nature* **298**, 325–326 (1982), the names of two individuals who contributed considerably to the work described were omitted: Drs K. O. Lloyd and L. J. Old of the Memorial Sloan Kettering Cancer Center, New York.

The following note relates to the letter 'Do graded units of accretionary spheroids from the Barberton Greenstone Belt indicate Archaean deep water environment?' by I. G. Stanistreet *et al.*, *Nature* **293**, 280–284 (1981). Interested readers are referred to the work of T. Heinrichs, Lithostratigraphische Untersuchungen in der Fig Tree Gruppe des Barberton Greenstone Belt zwischen Umsoli und Lomati, *Gottinger Arb. Geol. Paläont.* **22**, 119pp (1980), which was not available to the authors during the preparation of the above manuscript.

BOOK REVIEWS

Ruskin then, science now

Michael Rodgers

Wiley: One Hundred and Seventy five Years of Publishing. By John Hammond Moore. Pp.279. ISBN 0-471-86082-4. (Wiley: 1982.) £14.75, $25.

COMPANY histories are not written primarily for the general reader and this one, celebrating 175 years of publishing at Wiley, is no exception. Nevertheless there is much here that those interested in books and publishing will appreciate.

In addition to journals, professional, research and reference works, Wiley's list contains many well-known science textbooks. Tracing the evolution of that particular species, the college textbook, provides the most interesting strand of this story, beginning in the 1940s when the United States government enacted its GI Bill of Rights. This entitled veterans of the Second World War to educational assistance, thus boosting the demand for college textbooks that had begun in the early 1940s, which in its turn arose from the armed services' large-scale provision of technical training. The bonanza for American textbook publishers came to an abrupt end in 1948, and not simply because the last of the ex-GIs had completed their college education. Publishers then were not over-concerned with such details as planning, cost accounting, and pricing policies; escalating costs were not being passed on to their customers. The boom fostered complacency, since little effort was required to satisfy students prepared to put up with dull, old-fashioned textbooks; their successors straight from school were more particular. A difficult period of adjustment lay ahead: a familiar pattern to those who, like me, entered publishing (in the UK) at the tail-end of the golden age of the 1960s.

For John Wiley & Sons there was the added irony that they had been steadily building a list of impressive titles in corporate management, yet they seemed unable to put this body of wisdom into practice. Their own solution to the general problem besetting the industry was to enrol four executives in the Harvard Business School's Advanced Management Programme in 1953. By the end of that year the company president, Bradford Wiley, was himself at Harvard to study modern business methods, returning

> enthusiastic, business-oriented, hardnosed, and determined to concentrate his full energies on the *financial* aspects of publishing.

No doubt it was an interesting time for Wiley employees as the new brooms returned.

Textbooks in the early days were the result of the buckshot approach: the publication of books with a broad appeal that *might* be adapted to specific course needs. In the 1950s the search for the customer still began after a textbook had been produced. Andrew Ford, a Wiley traveller of that era, notes that

> Editors relied on advisers, series editors, consultants, boards, and so on. Just look at our catalogs of those years. Nothing but one series after another.

This may produce a wry smile from some of my contemporaries in British publishing: we started out doing much the same thing, though 20 years later.

Ford, brought into the office as a junior editor in 1957, found

> an academic-like atmosphere where chief editors kept top schools to themselves like prizes for seniority and only grudgingly gave approval to manuscripts procured by a new employee.

The vital role of basic introductory textbooks in providing a reliable — and substantial — backlist income was yet to be fully appreciated. This was to change, and the 1960s saw a striking increase in Wiley's share of the college market. In 1961 their list contained 18 college titles with annual sales of 10,000 copies or more; in 1971 the figure had risen to 46.

How do the really successful textbooks actually begin life? It is a chancy business, for all the talk of planning, with the right author and the right editor coming together just when the market is ready for what they will eventually develop. We are given a fascinating glimpse of the genesis of Halliday and Resnick's *Physics for Students of Science and Engineering,* one of the most famous of science textbooks. Towards the end of 1954 one of Wiley's college editors, Robert B. Polhemus, happened to be visiting Resnick at the University of Pittsburg. A number of publishers had been urging Resnick and his departmental colleague Halliday to turn their lecture notes into a textbook. Polhemus noted this in his report to the New York office, continuing:

> The idea has blown hot and cold. Right now it's cold, and Halliday told me afterwards that he has definitely decided against doing such a book.

But they did and the rest, as they say, is history. Published in 1960, the parent text and its various abridgements and supplements have sold almost two million copies.

One year later Wiley merged with Interscience Publishers, the creation of two Europeans, Maurits Dekker and Eric S. Proskauer. Their original aim had been to provide a European-style publishing house in New York for émigré scientists in America. When the firm was established in 1940, German chemistry texts were used throughout the world: one of the first Interscience titles was an English translation of Karrer's *Organic Chemistry.* Thirty years later roles had been reversed, with the translation of Cotton and Wilkinson's *Inorganic Chemistry* becoming the standard text in German universities.

The predictable question concerning Wiley's future is posed on the penultimate page. In the 1980s they expect more expansion in the professional, medical and international groups than in the educational group: a reflection of an increasing demand for technical skills in the Third World coupled with a stable, or declining, college population in the developed countries. Of course it is the electronic revolution that will affect the company's long-term prospects, and although there are no specific forecasts, companies such as Wiley will doubtless have no real trouble in coping with the impact of electronics on reference sources generally. The best textbooks are a different matter. The experience of reading them could not be created by resorting to a screen, and their development will always need individuals. It is easy for Wiley to maintain that a future with an increasingly professional management, executives who refer to books as "product", sophisticated market research, and all the rest, will not stifle individual enterprise, but we look to their next decades' activity to prove the point.

Wiley's birthday volume is written in an earnest, respectful style, as befits an official history, but there are plenty of good stories and anecdotes about the life and times of a company that once published James Fenimore Cooper and John Ruskin. One appealing story concerns a railroad fan, Andrew Neilly, who joined Wiley as a traveller in order to see the nation by train, and for two years (1947–1949) he did just that. It must have been fun. And good background too, for he ended up as company president. ☐

Michael Rodgers, formerly with Oxford University Press and W.H. Freeman, is joining Longmans after a brief spell at Nature.

The protocol for arranging nature

Michael B. Usher

Multivariate Analysis in Community Ecology. By Hugh G. Gauch Jr. Pp.298. Hbk ISBN 0-521-23820-X; pbk ISBN 0-521-28240-3. (Cambridge University Press: 1982.) Hbk £20, $37.50; pbk £7.95, $14.95.

ECOLOGISTS collect multivariate data. Very rapidly the number of observations, each being the occurrence or abundance of one of a large number of species in one of a large number of quadrats, baffles the observer, who needs some kind of protocol for arranging and viewing the data. Multivariate analyses provide that protocol, but the diversity of possible methodologies can confuse all but the most numerate of ecologists.

In this new book, Hugh Gauch attempts to explain the methodology of multivariate analysis without delving into the mathematical or computational complexities. The introductory chapter deals with hand sorting: the sceptic only needs to look at Table 1.2 with 50 species recorded from 25 quadrats to see how even a small data set can look incomprehensible until it is re-arranged, as in Table 1.3.

Gauch makes the point that more objective methods for arranging all of the individual observations are required, and he devotes the remainder of the book to discussion of the three basic approaches to sorting ecological data of this type — direct gradient analysis, ordination and classification. Although the structure of each chapter differs, generally the rationale of the approach is described, the methods are explained in words rather than in mathematical symbols, a number of examples are quoted (illustrations lead to a geometrical interpretation of the results), some of the known problems are described, and finally there is a broad evaluation. It is these chapters which give the book its value.

There are two drawbacks, however, that prevent this being a complete textbook. First, if anyone actually wishes to undertake an analysis they will have to turn to another book for the recipe. True, there is a two-page appendix included on computer programs, but this is too brief to be a usable consumer's guide. Second, the text is very Cornell-orientated — perhaps not surprisingly, since Gauch is closely associated with the group which worked with the late R. H. Whittaker at that university. An example is the "horseshoe" problem, where their DECORANA method of tackling it is described but others are not considered (though to be fair the extensive catalogue of applications in Chapter 6 partly overcomes this problem).

Nonetheless, the clear explanation and the comparisons between the various approaches make the book a suitable text for the student or researcher who wishes — or has — to understand this field of quantitative ecology. As the author in general cleverly avoids the mathematical complications, the apparent simplicity may be beguiling. But I still plan to use this book as a background text when teaching multivariate methods. ☐

Teaching machines

Margaret Boden

Intelligent Tutoring Systems. Edited by D. Sleeman and J.S. Brown. Pp.345. Hbk ISBN 0-12-648680-8. (Academic: 1982.) £19.20, $39.50.

INTELLIGENT tutoring systems (ITSs) are programmed teaching-aids grounded in artificial intelligence (AI). They differ radically from familiar types of computer-assisted-instruction (CAI). Many of the latter merely present repetitive "drill-and-practice" exercises; others can vary their response with the student's level of understanding by means of branched programs with predefined choice-points, but only to a very limited degree. ITSs are considerably more flexible, and better able to adapt to the idiosyncracies of a student's thinking.

This flexibility derives from the fact that ITSs contain complex computational models of students' knowledge and thinking. These control the questions and responses that an ITS presents to the student, and generate its diagnoses of students' mistakes. Unlike traditional CAI, the emphasis of ITSs is less on facts than on ways of thinking about a problem-domain; they function not so much by presenting "correct" examples of solutions as by providing relevant hints or questions, and — significantly — by diagnosing the thought-strategies behind the student's mistakes so as to guide the tutorial response.

Such diagnosis requires an understanding (in explicit, programmed, form) of the variations in cognitive structure and inference that underlie different sorts of (non-random) mistake. Computer science has a word for such mistakes — "bugs". A bug is a precisely definable and relatively systematic erroneous variation of a correct procedure (this definition, though, optimistically implies an underlying correctness). Much work on ITSs is focused on identifying and using bugs in the student's thinking.

For example, DEBUGGY is a program that is better than human beings at diag-

nosing the (nearly one hundred) different bugs that can explain a student's errors in doing subtraction. Its authors have provided a precise notation for describing these, and are also developing a "generative" theory of bugs — that is, one that can be applied to a particular (correct) procedural skill to generate all the bugs actually observed, and no others. This theory aims also to explain the pattern of bugs observed, so that (for example) two superficially different mistakes in subtraction can be understood as two variations of the same underlying difficulty in the student's mind. The ITS thus embodies a psychological theory predicting the detailed errors observed during learning.

But this program, like most of the other ITSs described in Sleeman and Brown's volume, could not be let loose in our schools tomorrow. This is partly because its psychological theory (like all current theories of learning) is inadequate to capture the full complexity of learning, and partly because AI cannot yet provide a "friendly" computing environment such that an untrained person (child or teacher) can use it. Given a specially-trained teacher, however, it can be used in the classroom to help identify precisely what is going awry in the children's thinking.

The complexity of the computational models within ITSs is such that they deal only with limited topics, as opposed to entire curricular courses (a further contrast between ITSs and CAI). Examples described in the book (which is edited by two pioneers in the field) include medical diagnosis of specific kinds, faults in electronic circuits, interpretation of magnetic resonance spectra and various mathematical topics. But the editors suggest that many of these forms of thinking are generally useful outside these particular applications — perhaps ITSs are the new Latin?

Sleeman and Brown's useful collection summarizes the state-of-the-art, and highlights problems as well as promises. They admit that current ITSs are excessively *ad hoc*, reflecting unprincipled intuitions about how to control their behaviour rather than well-founded psychological and computational theories about teaching–learning strategies. As well as improvements in AI techniques (for handling natural language dialogue, for example) we need more experimental investigation of how to transform students' misconceptions into constructive learning experiences. But ITSs could help direct the relevant research. One can thus endorse the editors' words:

> We hope that educational theorists will find the explicit formulation of tutoring, explanation and diagnostic processes inherent in ITSs a test bed for developing more precise theories of teaching and learning. ☐

Margaret A. Boden is Professor of Philosophy and Psychology at the University of Sussex.

Inside cytoplasm for outsiders

Harriet Harris

Organization of the Cytoplasm, Parts 1 and 2. *Cold Spring Harbor Symposia on Quantitative Biology*, Vol. XLVI. Pp.1,047. ISBN 0-87969-045-3. (Cold Spring Harbor Laboratory: 1982.) $130 (US), $156 (elsewhere).

One of the principal goals of cell biology is to describe the functions and behaviour of the living cell in terms of its molecular components. Even with the objective restricted to an understanding of the cytoplasm, however, the complexity of function and the number of constituent organelles and macromolecular components is daunting. Nonetheless the progress with certain specialized systems (such as eukaryotic flagellae or intestinal microvilli) towards the correlation of biochemistry, structural organization and dynamic function gives hope that the ultimate goal can be achieved.

The symposium on which these volumes are based brought together a wide diversity of topics, ranging from properties of bulk cytoplasm to details of molecular interactions. It would be fair to comment that relatively few of the contributors to the books might be described as studying cytoplasm *per se*, and it appears that one aim of the two-volume work is to stimulate a sense of common purpose between researchers in fields as distinct as, for example, membranes and microtubules.

The behaviour of living cytoplasm must provide the essential framework within which to view both ultrastructural and biochemical results. This field is being greatly stimulated by new techniques in light microscopy, sometimes in combination with the microinjection of foreign substances into the cytoplasm. These yield information on the movement of macromolecules and organelles through the cytoplasm, or may detect changes in important regulatory factors such as *p*H and calcium ion concentration. Such developments are still in their infancy, but offer the exciting possibility of enabling us to describe actual events in the cytoplasm, which is a vital step on the way to elucidating by what mechanisms such events occur.

A fruitful approach to mapping the spatial organization of the cytoplasm has been to localize known proteins within fixed cells by means of specific antibodies, for example, by immunofluorescence. Such techniques have been nowhere more productive than in the extensive characterization of three sets of cytoskeletal filaments — microtubules, intermediate (100Å) filaments and microfilaments — all of which are well represented in these volumes. A description of the location and composition of a structure, however, is not necessarily the key to comprehending its function, and an outstanding question on the cytoskeleton concerns the role of intermediate filaments. This problem is being tackled by microinjection of filament-specific antibodies to selectively dissociate the networks within living cells, an experimental approach which holds promise as a general method for probing elusive functions. Often the most useful data on the static organization of macromolecules are obtained with simplified systems. Two striking examples are the packing of actin filaments in stereocilia and the linkage of the cytoskeleton to membranes in erythrocytes, both of which provide general models applicable to less specialized cell types.

Another theme of the symposium, reflected in the books, concerned the mechanisms by which cytoplasmic order can be maintained in complex, multicomponent, dynamic systems. This is a speculative area and fertile ground for hypothetical models, but some highly productive experimental systems are also described. Protein-sorting problems are discussed by several authors, in a variety of contexts; these include selective insertion of proteins into or through membranes on synthesis, synthesis and expression of cell surface or secretory proteins, and selective uptake at the surface, all processes which may occur rapidly with continuous turnover and where high specificity is essential to deliver the proteins to their correct destinations. Other cytoplasmic components which may be in a highly dynamic state are the microfilaments and microtubules, where these form transient assemblies, such as the mitotic spindle. Assembly must be under rigorous control, since the correct location and polarity of filaments is essential in determining function. Current data indicate that order may be achieved by discrete organizing centres for filament growth, but these would only be effective in conjunction with the suppression of spontaneous, unregulated filament formation. A wealth of data from *in vitro* biochemical studies of filaments and their associated proteins generally support such a model, but proof of the effective modes of control *in vivo* will be more difficult to achieve.

What are the physiological switches signalling changes in cytoplasmic behaviour? Calcium, acting both directly and by calmodulin-mediated processes, including phosphorylation, is heavily implicated, as are cyclic AMP-dependent and other kinases. The space devoted to regulation in the books is disappointingly small, perhaps because the areas of ignorance are still too large for meaningful questions to be asked.

The attempt of the editors to unite a range of subjects under the single heading of cytoplasmic organization is timely, but not wholly successful. Fully comprehensive coverage of such a large field is not to be expected, even in a thousand pages, but the balance between different topics is in places very uneven. Only a handful of articles, for example, make any reference to the soluble components of the cytoplasm, but nearly half of the books (surely too much) is devoted to cytoplasmic filaments. These volumes do however contain a wealth of interesting material, while the breadth of ground covered makes them especially valuable to more general readers, or to cell biologists exploring areas peripheral to their own. □

Harriet Harris is at the Laboratory of Molecular Biology, Cambridge, UK.

All of the Araneae pulled together

J.L. Cloudsley-Thompson

Biology of Spiders. By R.F. Foelix. Pp.306. ISBN 0-674-07431-9. (Harvard University Press: 1982.) $35, £21.

ALTHOUGH there are some recent and quite excellent books on the ecology and natural history of arachnids in general and of spiders in particular, no new attempt has been made for over half a century to provide a comprehensive synthesis of the general biology of these fascinating creatures. The book under review, the original version of which appeared in 1979 as *Biologie der Spinnen* (published by Georg Thieme Verlag, Stuttgart), is an attempt to pull together the various facets of a spider's life. It is not a condensed handbook or reference book so much as an advanced introduction to the group.

Spiders are found throughout the world and, according to Rainer Foelix, "have conquered all ecological environments, with perhaps the single exception of the air": and, one might add, of the seas. The biology of freshwater spiders (*Argyroneta aquatica, Dolomedes* spp. etc.) is discussed in some detail, but little mention has been made of marine littoral spiders, although these do occur as well. It is, in truth, no exaggeration to say that all possible ecological niches on land have been occupied, including rather barren environments such as sand dunes, tidal zones or mountain tops. The distribution of spiders, extending even to oceanic islands, can be explained by the ability of the young of many species as well as of adult Linyphiidae, to float through the air, ballooning on their own threads. That spiders cannot bridge really large distances by aeronautical means, however, is indicated by the fact that East Africa and Madagascar are only 400 km apart, yet the spider fauna of each is quite different.

The interactions between spiders and their environments have been investigated systematically only within the past few decades. During this time, however, information about the ecology of spiders has burgeoned to such an extent that only a few selected themes have been discussed in the chapter on ecology. These include distribution, habitats, prey, enemies, thermoregulation, overwintering, camouflage and mimicry, communication and social behaviour. Other chapters are concerned with functional anatomy, metabolism, neurobiology, spider webs, locomotion and prey capture, reproduction, development, phylogeny and systematics.

The book is well illustrated with photographs and line drawings. It is interestingly written, and the author has managed to convey to the reader some of his own obvious enthusiasm for the subject. He cannot fail to have engendered further interest in spiders, thereby militating against the neglect they have so long been accorded and which he himself so deplores.

J.L. Cloudsley-Thompson is Professor of Zoology at Birkbeck College, University of London.

NEURO-TRANSMITTER AGONISTS FROM BIOSEARCH

BIOSEARCH offers a number of unique neurotransmitter agonists of recognized value. All are natural products isolated in our laboratories and are of exceeding purity.

Tectonics: moving with the times

Janet V. Watson

Plate Tectonics and Crustal Evolution, 2nd Edn. By Kent C. Condie. Pp.310. Hbk ISBN 0-08-028076-5; pbk ISBN 0-08-028075-7. (Pergamon: 1982.) Hbk £32.50, $65; pbk £13.10, $29.50.

SO MANY books have been written in the aftermath of the plate tectonic upheaval that any new arrival is bound to encounter some resistance. Kent Condie's volume is a second edition, issued six years after the original, and can therefore be said to have already justified its existence.

Has the new edition moved with the times? Although text, figures and tectonic map have been updated with respect to many details, my impression is that the book retains not only the merits but also the defects of its predecessor. Kent Condie is distinguished for his work on Precambrian magmatic assemblages, and his treatment of the Precambrian magmatic provinces and of igneous phenomena generally is thorough and effective. He is successful in showing how geophysical and geochemical data can contribute to the understanding of geological problems and he has been unusually courageous in his attempts to elicit a general picture from the scrappy and often contradictory evidence about the deep structure of the crust and mantle. The numbers assigned to such values as the average thicknesses of crust in different types of province make good Aunt Sallys for the knowledgeable, though the less-experienced reader might have been better served if a range rather than an average had been quoted.

The inequalities of standard of treatment seem more apparent in this second edition than they did in 1976. In particular the disparity between the sophisticated discussion of magmatic phenomena and the cursory treatment of sedimentary basins has become more glaring. The author justifies the omissions on the reasonable grounds of lack of space and on the need to avoid overlap with other published works. Nonetheless, plate tectonics without the sedimentation story is Hamlet with no more than half the Prince of Denmark.

I have one final personal regret which concerns the otherwise welcome world tectonic map which is contained in a pocket at the back of the book. Maps are not only valuable sources of information, they can also be objects of beauty that kindle the imagination and stimulate the ininitiated and the expert alike; this one succeeds in its first role but is sadly deficient in the second. □

Janet Watson is a Professor in the Department of Geology at Imperial College, University of London.

ANNOUNCEMENTS

Awards

The 1982 Kone Award has been awarded by the Association of Clinical Biochemists to **Professor Poul Astrup** (Copenhagen) for his contribution to clinical chemistry.

The winners of Columbia University's 1982 Louisa Gross Horwitz Prize are **Barbara McClintock** (Carnegie Institution's Genetic Research Unit at Cold Spring Harbor) and **Susumu Tonegawa** (Center for Cancer Research and the Department of Biology at the Massachusetts Institute of Technology).

The Lita Annenberg Hazen Award and Fellowship Grant aims to recognize major achievement and superior potential and to foster a greater commitment by physicians to clinical research. A prize of $50,000 (tax free) will be awarded to the physician-investigator or team of physicians for current and published work, that is of evident superiority and importance. A companion grant of $50,000 will be given to the investigator's institution for the support of a Research Fellow or Fellows whom the Award winner will select as associates. Further details from Mount Sinai School of Medicine of the City University of New York, Office of the Dean, 1 Gustave L. Levy Place, New York, New York 10029, USA.

Applications for training fellowships in 1983–84 are invited from junior scientists wishing to be trained in those aspects of cancer research related to the International Agency for Research on Cancer's programme: epidemiology, biostatistics and environmental carcinogenesis — both chemical and viral. Applicants should be engaged in research in medical or allied sciences and intend to pursue a career in cancer research. Fellowships are awarded for one year and are tenable at the Agency or in another suitable institution abroad. Further details from: the Head of the Research Training and Liaison Programme, International Agency for Research on Cancer, 150 cours Albert-Thomas, 69372 Lyon Cedex 08, France.

The National Physical Laboratory is to set up an Awards Scheme aimed at furthering knowledge and understanding of metrology. In 1983 single-payment awards of up to £5,000 will be made to individual scientists on the full-time academic staff of UK universities and polytechnics, who submit the best ideas and proposals for research and development work likely to lead to a major advancement in measurement. Applications should reach Dr K.C. Shotton, Secretary, NPL Metrology Awards Scheme, National Physical Laboratory, Teddington, Middlesex, UK, by 31 December 1982.

The Institution of Mechanical Engineers and Esso announce the Tribology Award 1982/83. A £300 prize will be given for an essay on industrial aspects of lubrication, friction or wear, submitted by 31 March 1983. Anyone under 35 engaged in industry or on a sandwich course may enter. Further details from. Mr J.H. Cole, Divisions Co-ordinator, The Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, London SW1, UK.

If you work in a university outside the UK, or in a polytechnic, college or school anywhere and your work is held up for lack of modest funding, the RSC Research Fund may be able to help you. Further details from: Mrs E.S. Wellingham, The Royal Society of Chemistry, Burlington House, London W1, UK.

Appointments

Mr Roland List (Canada) has been appointed Deputy Secretary General of the World Meteorological Organization (WMO) succeeding Raymond Jean Schneider (Switzerland) who has retired.

The new board of governors of the International Atomic Energy (IAEA) have elected the governor from Czechoslovakia, **Ambassador Emil Kebluser** to be Chairman from 1982 to 1983. The vice-chairmen are: **Luigi Noe** (Italy) and **Adolfo R. Taylhardat** (Venezuela). **Bernard Bechetoille** (France) is the new director of the Division of Budget and Finance.

The following appointments have been made within CSIRO: **Dr David Smiles** has become chief of the Division of Soils, based in Canberra; **Dr Don Gibson** is chief of the Division of Energy Technology in Melbourne; **Dr David Mitchell** is officer in charge of the Centre for Irrigation Research at Griffith in New South Wales; **Dr Alan Reid** is chief of the Division of Mineral Engineering in Melbourne.

Sir Keith Joseph, Secretary of State for Education and Science, has appointed three new members to the Natural Environment Research Council: **Lord Cranbrook, Professor Ronald Edwards** and **Professor John Simpson.** Reappointed are **Professor William Stewart, Mr Hugh Fish** and **Professor Bernard Leake.**

J. Mark Danley has been appointed Group Leader for Education and Training at BioSciences Information Service (BIOSIS).

Dr I. Kelsey Fry is the new president of the British Institute of Radiology 1982–83.

Mr John Banks has been appointed president of the Institution of Electrical Engineers (IEE). The retiring President is Sir Francis Tombs.

Dr Donald J. Reis has been chosen as the first George C. Cotzias Distinguished Professor of Neurology at Cornell University Medical College.

The French Minister of National Education has conferred the title of Doctor Honoris Causa of the University of Nancy on **Prof. A.R. Ubbelohde** (Imperial College, University of London).

The governing body of the Rowett Research Institute has appointed **Dr Philip James** to the post of director in succession to Sir Kenneth Blaxter.

Derek M. Lambert (Cyril Blumfield & Partners) has been appointed president of the Concrete Society.

Martin C. Steele, formerly in charge of the semiconductor electronics group at the General Motors Research Laboratory, has been appointed acting director of the Institute for Amorphous Studies, Michigan.

George A.M. Cross, formerly at the Wellcome Research Laboratories (Beckenham, UK) has been appointed a professor at The Rockefeller University to head a new laboratory of molecular parasitology.

Dr C.W. Davidson (Department of Electrical and Electronic Engineering at Heriot-Watt University) is the new chairman of the Institution of Electrical Engineers' Science, Education and Technology Division.

Meetings

7 December, **Plant Cell Culture,** London (S. Whittaker, Oyez Scientific and Technical Services Ltd, Bath House, Holborn Viaduct, London EC1, UK).

15-17 December, **Annual Meeting of the British Medical Ultrasound Society,** Sheffield (British Institute of Radiology, Institute House, 36 Portland Place, London W1, UK).

20-22 December, **Biochemistry of Carcinogenesis,** London (The Biochemical Society, 7 Warwick Court, High Holborn, London WC1, UK).

20-22 December, **The Detection and Measurement of Hazardous Substances in the Atmosphere,** London (Dr J.F. Gibson, The Royal Society of Chemistry, Burlington House, London W1, UK).

10-13 January 1983, **Development of the Vascular System,** London (The Ciba Foundation, 41 Portland Place, London W1, UK).

17-21 January, **CIMO Working Group on Upper-Air Technology Basic to User Needs**, Geneva (World Weather Watch Department, World Meteorological Office, Geneva, Switzerland).

25 January, **Radiological Protection — Future Research Requirements**, London (Prof. J.H. Martin, Dept of Medical Biophysics, Blackness Laboratory, University of Dundee, Dundee, UK).

7-11 February, **Water Hyacinth**, Hyderbad (Dr G. Thyagerajan, Regional Research Laboratory, Hyderabad 500 009, India).

13-18 February, **Recent Advances in Bone Marrow Transplantation**, Utah (UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024, USA).

16 February, **New Radiopharmaceuticals and their Clinical Applications**, London (The British Institute of Radiology, Institute House, 36 Portland Place, London W1, UK).

21-23 February, **Diet and Nutrition**, Tel Aviv (The Secretariat, International Conference on Diet and Nutrition, PO Box 29784, Tel Aviv, 61297, Israel).

21-25 February, **Cooperative Education**, Melbourne (The Chairman, World Conference on Cooperative Education, PO Box 218, Hawthorn, Victoria 3122, Australia).

1-4 March, **Space Physiology**, Toulouse (CNES, Department des Affaires Universitaires, 18 Ave Edouard-Belin, 31055 Toulouse Cedex, France).

21 February — 4 March, **Commission for Agricultural Meteorology**, Geneva (World Climate Programme Department, World Meteorological Organization, Geneva, Switzerland).

7-12 March, **Analytical Chemistry and Applied Spectroscopy**, Atlantic City (Pittsburgh Conference, 437 Donald Rd, Pittsburgh, Pennsylvania 15235, USA).

8-11 March, **Nickel in the Human Environment**, Lyon (Dr W. Davis, IARC, 150 cours Albert Thomas, 69372 Lyon Cedex 08, France).

9 March, **Digital Radiography**, London (The British Institute of Radiology, Institute House, 36 Portland Place, London W1, UK).

13-17 March, **Microlithography**, California (SPIE, PO Box 10, Bellingham, Washington 98227-0010, USA).

14-16 March, **Biomedical Research**, Heidelberg (Charles River Foundation, PO Box 430, Wilmington, Massachusetts 01887, USA).

14-17 March, **Microbiological Quality Assurance in Industry**, Brighton (Scientific Symposia Ltd, 33-35 Bowling Green Lane, London EC1, UK).

14-17 March, **Poliomyelitis Control**, Washington DC (Dr E.C. Chamberlayne, Fogarty International Center, Building 16A Room 205, National Institutes of Health, Bethesda, Maryland 20205, USA).

14-18 March, **Reactions and Intermediates in Nitrogen Fixation Processes**, Brighton (EUCHEM Conference, ARC Unit of Nitrogen Fixation, University of Sussex, Brighton, UK).

14-18 March, **Informal Coordination Meeting on the Use of INMARSAT**, Geneva (World Weather Watch Department, World Meteorological Organization, Geneva, Switzerland).

27-30 March, **1st European Symposium on Radiopharmacy and Radiopharmaceuticals**, Elsnore (Isotope Pharmacy, Frederikssundsvej 378, DK 2700 Copenhagen/Bronsho, Denmark).

21-25 March, **Annual American Society for Neurochemistry Meeting**, Honolulu (Dr G.R. Dutton, College of Medicine, University of Iowa, Iowa 52242, USA).

25-28 March, **British Society for Cell Biology**, Liverpool (Local Meeting Secretary, Dept of Medical Cell Biology, Liverpool University, UK).

26 March-1st April, **Gene Expression**, Park City (UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024, USA).

New ventures

The Arab Bureau of Education for the Gulf States has started publishing a new journal, entitled *The Arab Gulf Journal of Scientific Research* which will be devoted to research in basic and applied sciences. All communications should be directed to: Managing Editor, Arab Bureau of Education for the Gulf States, PO Box 3908, Riyadh, Saudi Arabia.

During the 18th General Assembly of the International Astronomical Union, a new IAU commission with the title: 'Commission 51 — Search for Extraterrestrial Life' was approved. The objectives will include: the search for planets around other stars; the search for radio transmissions, intentional or unintentional, of extraterrestrial origin; the search for biologically relevant interstellar molecules and the study of their formation processes; detection methods for potential spectroscopic evidence of biological activity; and finally the coordination of efforts in all these areas at the international level. Prof. Michael D. Papagiannis was elected President of the new commission and all IAU members who would like to join the new commission are requested to write to him at the Dept of Astronomy, Boston University, Boston, Massachusetts 02215, USA.

Following the First International Symposium on Radiation Physics, ISRP-1 (Calcutta 1974), interest has been expressed in forming an International Radiation Physics Society (IRPS) which could serve as the primary sponsor for further symposia in this interdisciplinary subject area. A protem committee has now been elected to explore and to take the necessary actions to form such a society. The primary objective of which society would be the global exchange and integration of scientific information pertaining to radiation physics, with emphasis on (1) research, theoretical and experimental, in the field of radiation physics, (2) investigations of the physical aspects of the interactions of radiation with living systems, (3) education in radiation physics and (4) utilization of radiation for peaceful purposes. Further information from Prof. D.F. Jackson, University of Surrey, Guildford, UK.

A new scientific society, the American Society for Virology, has been officially inauguarated with the first of what will be annual meetings. W.K. Joklik of Duke University, was elected president of the society. The major purpose of the society will be the organization of annual meetings; the 1983 meeting being scheduled for Michigan State University next summer.

The International Society of Cryptozoology aims to be a focal point for the investigation, analysis, publication, and discussion of all matters related to animals of unexpected form or size, or unexpected occurrence in time or space. The society will promote the scientific examination of all evidence related to these matters. Although the society is primarily intended for biological scientists, membership is open to all interested persons. The society will publish both a quarterly newsletter and a scholarly, refereed journal, entitled *Cryptozoology*, which will appear once a year. Further information can be obtained from J. Richard Greenwell, International Society of Cryptozoology, PO Box 43070, Tucson, Arizona 85733, USA.

The Agricultural Research Council is to establish an Animal Breeding Liaison Group within the Edinburgh School of Agriculture, under the leadership of Prof. J.W.B. King. Its role will be to identify problems of current concern within the animal breeding industry and to promote the rapid uptake of research into farming practice. The group will liaise closely with other research establishments and relevant industrial organizations. Further information from M.L.S. Delaney, Agricultural Research Council, 160 Great Portland St, London W1, UK.

Patching up the pipeline quarrel

The United States and Western European governments are trying to settle their quarrel about the Siberian pipeline. Their most important task is to find a way of rewriting the strategic embargo.

The great conflict between the United States and several industrial states in Western Europe about the pipeline intended to carry natural gas from the Soviet Union to the West seems to have entered a new phase — one in which statesmen wish they had behaved differently. Their immediate difficulty is that of knowing how best to retreat from positions they have established by earlier declarations that the pipeline dispute entails issues of principle that cannot be given up. The result is that a number of manufacturers that have supplied compressors for the Soviet pipeline are still on a kind of US blacklist, denied supplies of virtually anything from across the Atlantic. This circumstance is manifestly inequitable, if only because the dispute concerns not the companies themselves, which would have had to break binding contracts with the Soviet Union to fall in with the Regan Administration's wishes, but their national governments. By now, there are obvious signs that the United States would willingly climb down from the hot-tempered position it assumed in the summer, but that it must have in return an agreement with Western Europe on trade with Eastern Europe and the Soviet Union. On what grounds can such an agreement be drawn?

As with other disputes, confrontation is more easily arranged than mollifying settlement. Both sides, the United States and West European governments, are affronted by the way in which their quarrel has blown up. In Europe, there is a widespread view that Mr Reagan should have said more plainly how strongly he and his colleagues felt about European participation in the pipeline project when they had a chance to speak their minds at the Versailles summit meeting last June. The United States, by contrast, claims to have been injured by the French government, which is accused of having misled it, but that complaint is insubstantial. The French government has made no bones about its determination to help with the pipeline ever since M. Mitterrand's election as President. It would have been especially hard to change course at about the time that the Soviet Union, under the terms of an agreement with France on scientific and technical collaboration, was planning to put the first Frenchman into an orbit about the Earth.

The difficulty in deciding where to go from here stems from the complexity of the underlying issues, and of the disagreements of principle that attend them. The most serious difficulty is that of dealing with the philosophical conundrum of knowing what the economic relationship should be between militarily hostile powers, the Soviet Union on the one hand, the United States and most of Western Europe on the other. In the old days, nobody bothered very much. France and Britain traded their way through the Napoleonic wars without much difficulty. The discovery that international hostility has economic dimensions dates only from the First World War, and from the recognition then that nation states could be brought to their knees by being physically deprived of goods, commodities and manufactures. Since the Second World War, this doctrine has been elaborated, perhaps further than logic will allow. At various times, both the United States and Western European governments have sought to distinguish between different kinds of goods: commodities embodying high-technology (Cray computers) have been on the West's strategic embargo list, but other materials (wheat, or less advanced computers) have been free.

One of the novel considerations that colour US policy on relations with the Soviet Union is the recent recognition that the United States and Western Europe no longer have a monopoly of high technology (there is, after all, Japan), so that agreements that enable the Soviet Union to earn hard currency may make possible the purchase of high technology from outside the old magic circle. (This is the sense in which President Reagan is right to assert that his administration is not being inconsistent in agreeing that the farmers of the Middle West should continue to supply cereals to the Soviet Union, for that is a way of sucking up convertible currency, not for increasing the supply of it.) That calculation cannot, however, be central, even in Washington. If the pipeline does generate for the Soviet Union a steady cash flow in convertible currency, the result will most probably be an increase of general purchases from the West, wheat, meat, dietary fats at the top of the list but other simple manufactures as well. Especially because it is now plain that the Soviet Union will not have hard currency running out of its ears even when the pipeline is complete, and so will not be able to lavish support on its ambiguous (and dubious?) allies around the world, Washington's hard currency objection to the pipeline agreement is unconvincing.

Washington's argument can indeed be stood on its head. Detente in the sense of the early 1970s may be dead (with Afghanistan and, later, Poland), but the old struggle between two conflicting ideologies remains. So what better means of persuading Soviet governments and their dependants of the ideology that Adam Smith has been preaching for the past two centuries than to engage the Soviet Union in honest trade? Conversely, will not trade that is too tightly regulated put at risk whatever hope survives that the two systems may one day come to a durable understanding? In short, if the United States Administration is looking not for an agreement that it can present to Congress as a diplomatic triumph but for a basis for future understanding with Western Europe, it should stop complaining about the hard currency the Soviet Union will earn from building the pipeline.

The more substantial objection to European participation in that project is the complaint that Western Europe will become strategically dangerously dependent on the Soviet Union if it becomes too substantial a customer for Siberian gas. There is no denying that it is anomalous that governments planning how and where to give hospitality to a new generation of US missiles aimed at the Soviet Union should simultaneously be planning to make themselves to some degree dependent industrially on a natural product supplied from the Soviet Union. Quantitatively, the dependence of Western Europe on the pipeline will be marginal, but its symbolic significance cannot be ignored. Western Europe might therefore without dishonour agree with the Reagan Administration that participation in a second pipeline project could judiciously be postponed.

The much more difficult decision is how the West at large should regulate the transfer of high technology to the Soviet Union. The strategic embargo list is itself as anomalous as the central assumption on which it is repeatedly drawn up — that there is a hierarchy among different kinds of know-how, and that it is possible by means of, say, a strict embargo on trade in bicycles with gear-shifts to deny to some trading partner the opportunity ever to improve the performance of the direct-drive bicycles that he is allowed to buy in bulk. The same goes for mousetraps but

0028-0836/82/450093-02$01.00

also computing machinery. The moral is that the Reagan Administration should now be bending its efforts to devising a system for a strategic embargo in which forbidden exports are classified not by type and catalogue number but by the effort in research and development that would be required to turn them into militarily useful weapons. On past experience, the United States would be chancing its arm by aiming at an advantage in time of three years or thereabouts. Does the present administration have the courage to acknowledge that that is about the best that can be hoped for?

Blow cold, blow hot

A relaxation of austerity has benefited the British scientific enterprise; but strings are attached.

The conclusion that the British Secretary of State for Education and Science, Sir Keith Joseph, may in reality be a better minister than he likes it to be thought emerged earlier this week from the Chancellor of the Exchequer's forward look at public spending in the three years immediately ahead. Sir Keith seems to have won from the Treasury an extra £2 million, or 0.4 per cent, of the budgets of the research councils in the financial year immediately ahead (beginning on 1 April next year). But since, unexpectedly, it has become known that an extra £4 million will be spent next year on the British Antarctic Survey, there is no way of telling whether the Natural Environment Research Council (the survey's sponsor) will be deprived of a further £2 million. Plainly, all departments of state in the British government are still fighting the Falklands war (which is not to say that the Antarctic survey will not put the extra funds fallen into its lap to good use).

The more valuable component of the science budget for next year, as now amended by the British Treasury, is what was being said earlier this week about the special support to enable universities to recruit young people to academic posts. Sir Keith has already stolen £6 million from the budget of the Social Science Research Council for this purpose, but when that will become available is to some extent in the hands of the research council itself. Now the intention is that up to £10 million should be spent on the recruitment of talented people (mostly in the sciences) to posts in the universities. For the time being, the fact that it is by no means clear how the extra money will be spent will not shade the joy with which university campuses will be suffused. For the best part of a decade, British universities have been unable to recruit to their teaching staffs the talented people whom, in other times, they would have snapped up. Even the most secure among older academics now acknowledge their need of "young blood". So, it should be said, they should have done some time ago.

Apart from the uncertainty about the source of this extra money, and its duration, the only difficulty in what the Department of Education and Science was saying this week after the Chancellor's declaration was that some of the extra money to be channelled towards the universities will be spent on courses in information technology. Apparently Sir Keith Joseph has been listening to Mr Kenneth Baker, the minister of state at the Department of Industry with special responsibility in this field. While Mr Baker is dangerously oversold on this government's plan to install cable television in Britain any day now (see *Nature* 28 October, p.765), he is right to be plugging the virtues of the technology of information. The open question, which Sir Keith Joseph should be brooding about, is whether it is right (let alone proper) for the Department of Education and Science to be telling universities that they can have extra money provided that they toe some ministerially determined line. In their hearts they know they should resist, and collectively refuse the money. In their boots, they know there are enough among them who will accept to undermine whatever high-minded position the high-minded among them might adopt. In short, the universities are being told that there will be graduate courses on information technology even if individual universities see no need of them. Sir Keith's success in persuading the Chancellor of the Exchequer may, in other words, have designed a poisoned chalice for them all.

Do not foretell the future

The European Commission's futures research project has not seen the future; but nobody can.

In Brussels, FAST means "forecasting and assessment in the field of science and technology", and the European Community now has two substantial volumes of a report on the subject. Among the now copious literature of the future, the report stands out for its sanity — the guiding assumption is that there must be a way in which present economic troubles can be cured by intelligent research, development and capital investment. The document is also full of interest — there is an intelligent discussion of the changing pattern of employment under the influence of changing technology and of what the authors of the report repeatedly call "the international division of labour", usually in a European context. Moreover, recommendations as to where, in the whole field, research and development should be encouraged are not pulled like rabbits out of a hat but are, rather, preceded by a careful account of the present problems of European industries, from chemicals to construction. For all these virtues, however, the report is too disjointed to be persuasive. Worse still, it is unlikely to be the kind of touchstone for planning the future development of the European Community's research programme that the Commission hoped for when the work was set in hand three years ago.

The reasons for this disappointment are easily found, and are probably inescapable in any attempt such as this to foretell the future. First, the forecast provided, necessarily a projection of the present into future decades, is innocent of the surprises yet to come. In this spirit, the FAST report pays particular attention to two now fashionable fields in which technology is likely to have a profound effect on the character of society — information technology and biotechnology. Thus the report has much in common with other recent attempts to plan ahead in research and development, the attempt by a committee of the British Department of Industry to map out a programme of research and development in information technology, for example. Thus, while some seers have for years been prophesying that biotechnology will be important, it is less than ten years since the prospect became as substantial as it is now. Nobody can be blamed, but even the specific account of the future now offered must overlook the technologies that have not yet emerged. A further snag is that committees are now well placed to plan the future strategy of research. Yet while committees have been saying for the past thirty years that the closing decades of this century would be dominated by the technology of telecommunications and computers, it has never previously been possible to spell out just how a government or a corporation should seek to profit from the likely course of development.

For such reasons, it is to be hoped that the European Community as a whole will take most to heart those features of the report now published that deal with structural questions, not the details of which research and development projects are likely to be most valuable in the years ahead. First, there is an urgent need for more incentives, within the Community, for a rational division of labour that will allow the most efficient producers to produce most. Although there has recently been some progress in throwing public purchasing open to all European companies, governments are still able to drag their feet in the interests of chauvinism — and as a result undermine their own long-term prosperity. Similarly, there is an urgent need somehow to make the European system of higher education and technical training more flexible, and to encourage mobility within it. Here again, chauvinism, if not outright xenophobia, is still all too common within Europe. But would it not make great sense that Europe should, for example, work towards some common university system? On both counts, alas, the obvious objection is that if some nations gained from a more efficient division of labour, others would lose. The answer is that this is not a "zero-sum game" but one in which the wealth of Europe as a whole would be improved.

Further snag with Stanford patent

Filing error claimed in Cohen–Boyer

Washington

The second Cohen–Boyer patent covering basic processes in genetic engineering may have suffered another setback last week when attorneys for the applicants admitted that there is a serious error in the patent specifications.

The error was one of several potential flaws cited by the US Patent and Trademark Office when, in August, it suddenly reversed its previous decision and decided to reject the patent (see *Nature* 12 August, p.595). Responding just one day before a deadline of 2 November, Stanford University and the University of California concede the error, but argue that the patent is nonetheless valid.

Their response, however, may raise more questions than it answers. Attorney Bertram Rowland, representing the universities, does not explain why he failed to inform the patent office of the error, which, he admits, "was known to the applicants' attorney as early as December 1977". And the two lines of defence he introduces in support of the patent's validity may well be disputed.

Rowland argues that despite the error, the patent office should withdraw its objections and grant the patent, and he offers two lines of defence for that argument. The first is that even "if applicants had not actually performed any of the experiments described in the experimental section . . . the specification would be enabling (sufficient to allow duplication and thus be patentable), since it teaches how to obtain and clone a functional plasmid containing foreign DNA". In other words, pSC101 is not itself vital, as the instructions provided in the patent explain how to select, isolate and use other suitable plasmids. "Testimonials" from molecular biologists Donald Helinski, Stanley Falkow and Bernard Weisblum are included to buttress the claim that anyone with "ordinary skill" in the field could, since 4 November 1974, have used the patent to prepare a functional plasmid — even without the benefit of a correct recipe for pSC101.

Yet in a submission to the patent office on 24 June 1977, Rowland seemed to take the opposite view — that pSC101 was indeed vital to the patent claims, and that this "new plasmid found by the inventors" was what distinguished their claims from potentially competing work by others.

The second line of defence offered by Rowland is that even if pSC101 is the key, the patent does not need to disclose how to make it since pSC101 was publicly available at the filing date. A declaration by Cohen, included in the response, states that he made the plasmid available to scientists, subject to two restrictions: "that it would not be passed on; that it should not be used in experiments believed at the time to have the potential to be dangerous". Cohen asserts that "no-one who requested pSC101 was denied pSC101" and that it was thus "widely available".

One patent attorney familiar with the case said that Cohen's restrictions on distribution of the plasmid may defeat this defence; to be safe, he should have deposited the plasmid in a recognized public repository such as the American Type Culture Collection before filing. This was not done until 25 June 1981, six months after the first patent was granted.

Rowland's admission of the error in the second patent application raises a potentially explosive question: should the first patent, which contains the same flaw, be reissued to correct it? Given the problems with the second patent, this is something Stanford would like to avoid. In an interview last week, Rowland tried to avoid the issue, saying, "Given that 99 per cent or more of the people in the field are aware of the situation [the error in the pSC101 recipe], whether I should have to go to the expense of filing for reissuance is an open question". He added, "I don't

Rowland's concession concerns an article published in November 1977 by co-inventor Stanley Cohen and a co-worker (Cohen, S.N. & Chang, A.C.Y. *J. Bact.* 132, 734; 1977) which contradicts the recipe set out in the patent for making pSC101, the key plasmid used for inserting foreign DNA into *Escherichia coli.* "pSC101 could not be prepared in accordance with the working example", Rowland writes.

The *Journal of Bacteriology* article came to the attention of the patent office only this summer, apparently through an article by an Exxon patent attorney, Albert Halluin. In several footnotes to a chapter he contributed to *The Patenting of Life Forms,* a book published in August by Cold Spring Harbor Laboratory, Halluin cites that article and other potential flaws in the patent. Rowland, after admitting that he knew of the existence of Cohen's article five years ago, writes that "I have no recollection as to why it was not brought to the Examiner's attention in the written record". The patent application was filed on 4 November 1974; it was later split into two parts, and the first patent was granted on 2 December 1980.

UK research councils' budget break

British research councils were told this week how much money they will get next year, but not which council is getting what — surely a formula for a scrap until the detailed allocations are announced in a few weeks' time.

According to Sir Keith Joseph, UK Secretary of State for Education and Science, who made a statement to the House of Commons on Monday, the total to be made available is £509.7 million, a shade above the £507 million requested by the Advisory Board for the Research Councils (ABRC) a few weeks ago (see *Nature* 4 November, p.7) However, the new figure includes a Falklands factor — an extra £4 million for the British Antarctic Survey (BAS), in line with policy announced after the Falklands conflict to increase research in the Antarctic. BAS is a component institute of the Natural Environment Research Council (NERC). NERC would welcome the sum as a gift, a spokesman said this week, but would be worried if it were to be subtracted from its planned budget for other science, or from that of other research councils.

Another unresolved issue is the position of the Agricultural Research Council, which has protested against ABRC's recommendation to hold its budget constant in cash terms for the next three years at £46 million.

As for the Social Science Research Council, "a small portion" of the £6 million cut threatened recently by Sir Keith Joseph will fall this year, with more to come in the next two years. It will contribute to a £14 million fund to provide "the first instalment of a programme for new technologies, including the recruitment of young researchers". Of this, £4 million will go to establish courses in information technology in technical colleges and polytechnics. The remaining £10 million is for new blood as well as for the provision of courses in new technologies "primarily to improve the supply of manpower in information technology". Moreover, part of the sum will be allocated not by the University Grants Committee and the universities, but by the research councils, said Sir Keith. So it is impossible to determine exactly how many jobs this £10 million will make available. A separate announcement will give details.

As for the universities themselves, they will enjoy a small increase in their grant for the present academic year (1982–83) from £1,137 million to £1,150 million, and the recurrent grant for 1983–84 will be set at £1,213 million. These figures are fixed in cash terms, and assume a salary increase of only 3.5 per cent. **Robert Walgate**

0028-0836/82/450095-02$01.00

know any law that says I have to''.

One old question that has resurfaced in the latest exchange between Stanford and the patent office, and that may bear on the first patent, is whether Cohen and Boyer are the sole inventors, as Stanford and the University of California claim. In its notice of rejection on 2 August, the patent office cites a statement by Dr Robert Helling — a co-author of the 1973 paper in the *Proceedings of the National Academy of Sciences* that is the basis of the patents that appeared in a news story in the 3 April 1980 issue of *Nature* (p.388). Helling, now at the University of Michigan, is quoted as refusing to sign a disclaimer of inventorship as requested by Rowland.

Helling has not, however, pressed any claims to date. And Rowland, in his response to the patent office, asserts that Cohen and Boyer are the sole inventors, having conceived the idea at ''a now famous delicatessen in Hawaii'' during a scientific meeting in November 1972. This, Rowland writes, rebuts ''any implication that the refusal to sign a disclaimer might be equated with an allegation of co-inventorship''.

But Helling told me last week ''I certainly am a co-inventor. The three of us were equal partners. I went out there to develop new cloning procedures; Herb (Boyer) was the one who suggested using plasmids, and asked me if Stan (Cohen) could join us''. Helling worked with Boyer at the University of California at San Francisco during his 1972-73 sabbatical.

Helling has been discussing the matter with the University of Michigan's attorney and said ''we may do something now'', but declined to give any details. A call to the attorney was not returned.

Although a recent court decision overturns the patent office's policy of considering co-authorship *prima facie* evidence of co-inventorship, Helling's statement in the 1980 *Nature* story complicates the matter.

Rene Tegtmeyer, the assistant commissioner for patents, said his office will act ''promptly'' on the case, perhaps reaching a decision within ''two or four weeks''. If the patent office stands by its rejection on 2 August, Stanford will then have three months to file a request for reconsideration or a notice of appeal to the Patent Office Board of Appeals. A decision might not be reached before the summer of 1984 — and the case could go on still longer if the board's decision were to be referred to the Court of Appeals for the Federal Circuit.

Stephen Budiansky

Science and Engineering Research Council

Big money for big science?

A potentially important difference of emphasis between the British Science and Engineering Research Council (SERC) and the Advisory Board for the Research Councils (ABRC) was apparent at the publication of the research council's report (HMSO, £4) last week. For while the advisory board said in its advice to the Secretary of State for Education and Science that the time had come to halt the retreat from Big Science (see *Nature* 4 November, p.1) SERC chairman Professor John Kingsman refers to ''broadening out from the support of 'big science' to a better spread of science and engineering''. Kingsman says that the advisory board's recommendation would be only one element in the council's decision how best to spend its money next year.

SERC's principal area of concern is the dual-support system through which funds for science research are provided jointly through the University Grants Committee (UGC) and the research councils. The SERC report says little about how far SERC is prepared to go to compensate for the dwindling UGC contribution, but also claims that ''the quantity and quality of research grant applications are being maintained''.

Professor I. Butterworth, chairman of SERC's Nuclear Physics Board, is more pointed, saying that the board wants SERC to provide a certain number of permanent posts in nuclear physics attached to universities until UGC is once again able to play its part.

Since 1978, the proportion of support for nuclear physics within SERC's overall budget has dropped from more than 30 per cent to about 20 per cent. The intended opening at Daresbury of the Nuclear Structure Facility (a heavy-ion accelerator) after an extended delay will provide some stimulus but, according to Professor Butterworth, its full utilization will be delayed. There is also a fear that if full support is given to LEP, the electron-positron collider at CERN in Geneva, it may not be possible to fund other particle physics experiments.

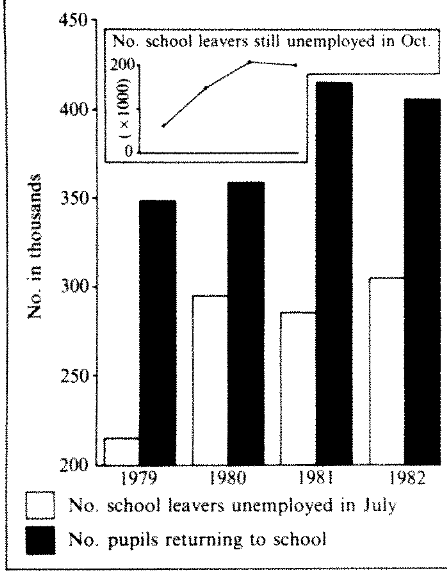
To judge from the report, physicists are also concerned that support for such fields as atomic spectroscopy, semiconductor research, superfluidity and superconductivity appeared to be decreasing relative to such fields as biology, chemistry and applied mathematics. Apparently a special committee has been considering criteria to be used in deciding the relative balance of support between different fields, but its conclusions have not been made public. And there is a possibility that the Synchrotron Radiation Source at Daresbury, from which X-ray spectroscopists have derived particular benefit, may be affected by rising costs, which may make necessary a choice by the Science Board between research grants on the one hand and further development and general support of central facilities on the other.

Support for information technology and space science, both recommended by the Advisory Board for the Research Councils, are, however, both booming at SERC. The two fields are beginning to link up, with the recent development of remote control of telescopes via satellite links between the Royal Greenwich Observatory and telescopes in Hawaii. Such developments might pay for themselves in reduced travel budgets for astronomers.

On the more contentious issue of the use of the South African Observatory (see *Nature* 23 September, p.291), the council says it is not in the business of taking political decisions at the expense of the interests of science and that, moreover, it had felt little pressure from the community and none from the government to sever its links with its South African equivalent.

The press conference called by SERC was made all the more bland by the decision not to make the report available in advance. Thus SERC, proud of its autonomy, has followed a government directive resulting from the premature publication in the national press of details of medals awarded for the Falklands fighting.

Philip Campbell



As the probability of long-term unemployment for the British school leaver has increased (reflected in the October unemployment figures), the number of pupils returning for further education has gone up. There has been no increase in resources made available to schools and extra pupils are being swallowed up by existing classes. However, fears that this would lower the standard at GCE 'O' and 'A' level are not borne out by statistics published by the examining boards, which show no real change in the pass rate during this period. The decline in numbers returning to school in 1982 is at least partly due to the rapid expansion of the Youth Opportunities Programme during 1981-82 from 360,000 to 553,000.

US elections

Key posts held

Washington

Last week's congressional elections, which gave the Democrats a 26-seat gain in the House of Representatives, returned all but two of the senators and congressmen who hold key positions on science and environment committees. The two losers were Senator Howard Cannon (Democrat, Nevada), the ranking Democrat on the Commerce, Science and Transportation Committee, and Senator Harrison Schmitt (Republican, New Mexico), a former astronaut and the only PhD scientist running for the Senate.

Cannon, who lost in a close race in his increasingly Republican state, has been a senator for 24 years. He was recently instrumental in pushing through legislation to guarantee continued funding of the Landsat remote-sensing programme.

Schmitt, who is completing his first term, has been a staunch supporter of President Reagan's economic policies, although he recently went against the Administration in sponsoring legislation to increase spending on science education. Schmitt also supported a shift in funding from the Department of Defense to the National Aeronautics and Space Administration for shuttle operations and for increased space and aeronautics research.

Three supporters of environmental legislation in the Senate who faced strong opposition in the election will all be back: Robert Stafford (Republican, Vermont), George Mitchell (Democrat, Maine) and John Chafee (Republican, Rhode Island).

In the House of Representatives, all the key players on science and the environment committees will be returning, although George Brown (Democrat, California), a strong advocate of science education and research, was pushed to sending out a plea during the campaign for financial support from scientists and educators.

At the other extreme, Senator William Proxmire (Democrat, Wisconsin) of Golden Fleece Award fame proved much more popular among his constituents than among the nation's scientists. He wound up with 64 per cent of the vote, having spent less than $150 on his re-election campaign.

A resolution calling for immediate negotiations toward a bilateral nuclear freeze was passed in eight states. Although the resolutions are not binding, the Reagan Administration had campaigned heavily for their defeat, arguing that a freeze would endanger US security. Voters in Massachusetts, Michigan, Montana, New Jersey, North Dakota, Oregon and Rhode Island passed the measure by a wide margin. It narrowly passed in California and failed in Arizona, the only other state where it was on the ballot paper.

Stephen Budiansky

West Germany science

Federal plans

The implications for science of the change in government in West Germany are emerging only gradually. The new CDU/CSU/FDP coalition is clearly going to be cautious in what it does at least until after the federal election next March. In any case, the vast and decentralized structure of German science makes it impossible to implement changes quickly. An indication of the new team's plans has been given by Dr Heinz Riesenhuber, CDU minister at the Research and Technology Ministry (BMFT) in speeches at a joint industry/BMFT seminar on technology transfer and at a meeting of the Fraunhofer-Gesellschaft in Munich.

Dr Riesenhuber made it clear that direct support of individual projects will be run down in favour of indirect support through tax relief, low interest loans, allowances and subsidies. The rundown can be seen as a continuation of the previous administration's policy under which barely half as many projects were started in 1981 as in 1979. Dr Riesenhuber hopes that indirect support will encourage more market-oriented research and he singled out the energy saving programme for particular criticism, saying that the returns for the DM 4,350 million (US $1,700 million) spent are quite inadequate.

In a similar vein, at the technology transfer meeting, the minister demanded that work at the 12 large state-supported research centres should concentrate more on market-oriented work and suggested that there should be more independent co-operation between research and industry. He expressed a belief that there is a pool of research results which could lead to industrial innovation at little or no cost. This seems questionable, for while it may have been possible to carry out development on a shoestring fifty years ago, modern requirements for quality and reliability in products and processes have made the step from research to production both expensive and time-consuming. If Reisenhuber's pronouncements are a foretaste of the kind of shift in emphasis that has occurred in science budgets in the United Kingdom and in the United States during the past decade, scientists working in basic research and on long-term projects will have to fight hard for their corners.

In more concrete terms, the draft budget for 1983 shows that the immediate effects will be small. The total research budget is DM 6,911.8 million (US $2,710 million), a decrease of 2.4 per cent compared with the draft budget of the previous government and of about 2.2 per cent compared with 1982. Details have not yet been announced and the proposals may be modified when they are discussed in the Bundestag on 11 November.

J.S. Dunnett

Interferon therapy

Side effect scare hits French trials

Paris

Four patients out of eleven being treated for cancer with French alpha-interferon have died from the same cause this year in France — myocardial infarction, a failure of a section of heart muscle through the loss of local blood supply. As a result, Jack Ralite, the French minister of health, has cancelled the trials, at least until Institut Pasteur Production (IPP), which produces the drug, can repurify its stocks and perform new toxicity tests on the material.

The deaths could be attributable to the interferon itself, or to impurities in it, or it could be just a run of bad luck. Several other countries are performing human trials with interferon and there have been no reports of the heart disease syndrome, and IPP uses essentially the same production method as Dr Kari Cantell, who has supplied much of the world's alpha-interferon: extraction from blood-bank leukocytes.

But the sequence of four similar deaths was too much to ignore. The scientific council which was set up to advise Ralite specifically on trials with the IPP interferon (the only French source) advised him to halt the trials. According to the president of the council, medical statistician Professor Robert Flamant, suspicions were first raised when the first two patients both died of myocardial infarction near the end of their treatment. They were both women 50–60 years old with acute breast cancer, who had been treated by other drugs and with radiation. The deaths led to "discussions" in the council, but they were dismissed as coincidence.

There was no problem with the third patient treated — nor any cure. But the fourth, a kidney cancer case, died of myocardial infarction actually during one of the interferon infusions.

At this point the council decided to change the method of introduction of the drug, which until then had been the "more aggressive" intravenous route rather than the intramuscular route which is usually preferred but which limits the size of the doses. This was fine for six patients, but in the seventh, with a slight increase of dose, there was another myocardial infarction. It was "less clear" in this case that interferon might be to blame, as the patient had a history of slight heart trouble. But it was enough to lead the council to stop the tests, especially since they also noted that a child had suffered great shock — and just survived — when given an injection of the interferon for a virus infection.

Flamant, however, expects his council to reauthorize the trials when IPP has repurified its stock (leukocyte interferon is always contaminated with various other proteins besides interferon) and if the toxicity trials — to be performed on dogs — are completed successfully. This may take two months, he estimates.

There is anxiety, however, about non-French interferon, over which Flamant's council and the minister himself have little or no control. The council deals specifically and solely with IPP interferon because it arose as a *quid pro quo* when the government first offered a guaranteed market to IPP for its product. Having guaranteed the cash, the government also wanted to ensure proper statistical control of the trials and so established the council.

But non-French interferon enters the country with no more than an import licence — and some of it, it is suspected, without any licence at all. This foreign interferon is being used for phase 1 and phase 2 human trials without any control, and with little knowledge on the part of the ministry.

It is therefore being suggested that the foreign interferon material, and other experimental drugs as well, should be controlled under a comprehensive oversight scheme. Thus questions raised over the purity of a particular kind of French interferon may also affect other drugs, both French and foreign.

Robert Walgate

Anglo-Australian bomb tests

Government traces victims

Canberra

It seems that the dust has not settled over Maralinga or at a site 200 kilometres to the north of it called Emu, both in South Australia, nor over the Monte Bello Islands off the coast of Western Australia. It was in these remote spots that the British government conducted a series of 12 atom bomb tests between 1952 and 1957 (see table). In addition, in the following six years, weapon experiments involving radioactive fallout, though not from explosions, were undertaken at the testing range of Maralinga — an aboriginal word meaning "field of thunder".

The federal government is now trying to trace people associated with the tests, some 15,000 in all, in order to establish if there might be a link between mortality and morbidity of this group and the tests. On 22 October, the Minister for National Development and Energy, Senator Sir John Carrick, announced that questionnaires seeking medical data were sent to all the 8,000 people whose whereabouts are known through sifting administrative records, and he appealed for help to find the rest. The Department of National Development and Energy, which is conducting the survey, is also unearthing death certificates for information on the number and causes of death among this population. Furthermore, the government commissioned an independent body of experts, the Australian Ionising Radiation Advisory Council (AIRAC), to examine the adequacy of safety precautions at the time and the possibility of ill effects from fallout. This report, now in its final draft, was expected to be released in a month but it will now be delayed until next year, partly because it contains some classified information awaiting clearance by British authorities.

The survey is both a response to and an attempt to allay growing public disquiet in the past three years over newspaper reports, mainly from South Australia, of illness and death among servicemen involved in the tests. Another story, just as alarming, which may not be apocryphal, is about a tribe of the Pitjantjatara aboriginals wandering into ground zeros during the tests unbeknown to the British. An attempt by the South Australian Health Commission to authenticate that claim only served to highlight the difficulties of obtaining information from a small nomadic and dispersed group and the lack of control data for comparison.

Of the many compensation claims lodged at the office of the commissioner for employee compensation, liability has been acknowledged in 5 cases — 3 for deaths from cancer, 1 for the aggravation of an existing nervous complaint, and 1 for a thyroid disease. The largest sum, A$32,000, was paid to the widow of Mr Frank Eaglen who died of cancer. Claimants are aided by the fact that the onus of proof rests with the government.

Australia and the United Kingdom agreed to establish a testing range at Maralinga in August 1954 and it was approved by cabinet in May 1955. Subsequently the Atomic Weapons Safety Committee was instituted, whose job it was to ensure that the tests were conducted to the satisfaction of the Australian government. This committee of scientists had the power to veto, until the moment of firing, any test not meeting its safety criteria. After its closure, the range was partially decontaminated in 1964 and again in 1967 (operation "Brumby") by British teams. However, as a consequence of Australia's ratification of the nuclear non-proliferation treaty, Britain was asked to "repatriate" half a kilogramme of plutonium existing as a single discrete mass buried at Maralinga and the material was removed in 1979, the same year in which the Department of National Development and Energy completed a programme of waste management and rehabilitation in accordance with AIRAC recommendations.

Radiation exposure

Unions agree

A scheme for compensating the dependants of radiation workers who have died from cancer has been agreed between British Nuclear Fuels Ltd (BNFL) and its trade and staff unions. The scheme will apply to present and past employees, but requires that dependants will be eligible for compensation only if there is evidence that the cancer may have been caused by occupational radiation exposure.

British Nuclear Fuels is the publicly owned monopoly for reprocessing and fabricating nuclear fuel. The distinctive feature of the new agreement is that compensation will be determined by the probability that a cancer has been induced by radiation, thus avoiding the "all or nothing" conundrum that has complicated earlier legal cases.

The scheme is hailed as a "pioneering deal" by Mr John Edmonds, National Energy Officer of the General and Municipal Workers Union (the main union involved in the negotiations). It is certainly a unique scheme in the nuclear industry, although large employers in other industries run compensation schemes that work along similar lines. Previous claims in respect of radiation-induced disease made through the courts have resulted in very long delays in payments; several substantial out of court settlements have been made.

The new procedure is voluntary, but the unions involved will recommend claimants to make use of the scheme. The option of taking a case to court instead is not

0028-0836/82/450098-02$01 00

excluded, and a compensation payment under the new procedure does not constitute an admission of liability by BNFL.

BNFL is to examine radiation dosage records of its employees at Sellafield (formerly Windscale) and its other plants, and will include employees of its predecessors in the field, the Atomic Energy Authority and the Ministry of Supply, going back to 1950. A BNFL spokesman, while emphasizing the company's continuing efforts to minimize radiation exposure among its employees, estimated that between 10 and 40 additional payments are expected immediately under the new scheme.

In difficult cases an independent panel of experts, jointly appointed by BNFL and the unions and under the chairmanship of Lord Gregson, will decide the level of compensation. The agreement is provisionally scheduled to last for two years and will be extended if it proves successful. It is also hoped that it might be possible to extend the scheme to cover cases in which radioactive material has been ingested (more difficult to assess for technical reasons) and cases of disablement. **Tim Beardsley**

EEC research council

British block safety reactor

Brussels

An otherwise successful meeting of the EEC's research ministers in Brussels last week was marred by some tough British objections to the new budget put forward by the Commission for the Super-Sara project. The project, which aims to explore ways of managing crises in light water reactors when loss of coolant takes place, is included in the new four-year (1982–86) programme for the EEC's joint research centres (JRC). Super-Sara will absorb a considerable part of JRC's budget at a time when efforts are being made to restructure its work so that it is more in line with other research and development aims of the Community.

Super-Sara was first proposed after the Three Mile Island accident and when the Italians wished to find a use for the Essor experimental reactor which was no longer being used at the Ispra Research Centre. Since then the enthusiasm of the rest of the member states, never very strong, has waned considerably as the original cost estimates have been continually revised upwards. British officials were predicting before Thursday's council that the project could be scrapped and even now its future is by no means certain.

A decision will have to be taken by Coreper, the committee of the member states' ambassadors, within the next two weeks before the revision of the 1982 budget is completed. Mr David Mellors, British Under-Secretary of State for the Department of Energy, has now asked the European Commission to present further details on how the increased project costs can be accommodated and has questioned whether the project, which he thought had been badly managed until now, could still be considered cost-effective.

Mellors said that the results that the project would yield could not be considered essential since it investigated only an extremely unlikely type of malfunction. The Commission has, however, received support from a task force of experts whose report concluded that the project was worthwhile and fitted into the matrix of research being carried out elsewhere. And even the United States has until now shown interest in contributing to the cost of the project. British opposition might be rooted in national interests because, having chosen to build pressurized water reactors, the United Kingdom will be only marginally interested in the results of the project.

Considerable confusion however, surrounds, the various estimates of Super-Sara's cost. An early estimate of 139.53 million European currency units to cover the project until 1988 has been constantly revised, standing now at 293.9 million units (£161.7 million).

European Commissioner Viscount Etienne Davignon told the ministers that 10 million ECU and 17.5 million ECU urgently needed to be taken from the 1982 revised and 1983 budgets respectively, plus a further 15 million ECU each for 1984, 1985 and 1986, if the project was to continue at all. He also pointed out that more delays will increase the cost of the project still further and that the cost of closing down the Essor reactor would not be cheap either.

Part of the explanation for the dramatic rise in cost estimates lies with the nature of the revision of JRC's programmes. Next year will be a special bridging year between the last programme (1980–83) and the 1984–87 programme. More staff are being recruited and 161 new posts are being created, 81 of them for the Super-Sara project, although the Commission claims that this is a temporary expansion to cope with the expected retirement of senior scientists. It now seems likely that instead of new staff being engaged there will have to be redeployment of staff among JRCs and national laboratories or certain other projects or plans will have to be curtailed such as the increase in JRC research asked for in nuclear energy. Except for the possibility of the number of experiments being reduced, there appears to be very little room for compromise over Super-Sara itself, and the British are worried about putting too many eggs in one basket. Even under present calculations, the fast breeder safety and the fuel cycle safety programmes are being cut back.

Jasper Becker

Thermonuclear fusion

Padua approved

Brussels

It is now virtually certain that the reversed field experiment (RFX) which was originally to be funded by the UK Atomic Energy Authority at the fusion research centre at Culham, will be taken on by the Italian Comitato Nazionale Delle Richerche and built at its laboratories in Padua. The consultative committee of the fusion programme was given the go-ahead to both this project and the construction of the Wendelstein VII advanced stellarator project, to be built at the Garching Laboratory of the Institut für Plasmaphysic in Germany.

Researchers were disappointed last year when the British government decided that there was no room in Culham's budget for the British contribution to the experiment of 16.5 million European currency units (ECU, 1 ECU = 55p). RFX is a direct descendant of ZETA — the zero energy thermonuclear apparatus — which hit the headlines in the late 1950s when it failed to achieve fusion for reasons which were not understood for some years. G.B. Taylor in the next decade proposed the reverse field theory to explain the failure and it was hoped that Britain could continue to lead the world in this field.

Reversed field pinch is one of the three options for achieving fusion which are being pursued in Europe under the Community's research programme. The experiment which will now be started in Padua will involve the construction of a 2,000 kA machine which will enable the experimenters to achieve a longer plasma confinement time. Padua had in 1978 been successful with a much smaller machine, known as ETA-BETA, capable of producing plasma currents up to 250 kA.

The project will still involve staff from Culham but the Italians will be providing the bulk of the cost of the experiment, some 15.7 million ECU, which will start next year and cover about four and a half years. The Community's budget will meet the rest of the cost, totalling 28.5 million ECU although this may rise, depending on whether the US Department of Energy is still willing to contribute to the cost of the project.

Officials in Brussels are, however, confident that the project may now go ahead without further setbacks. In fact, there may be advantages in siting the experiment in Padua where it will not have to play second string to the JET tokamak.

The Wendelstein VII advanced stellarator project will be the first stellarator to use modular twisted coils instead of helical windings to create the poloidal half of the magnetic field that heats and compresses the plasma. The stellarator will cost 12 million ECU to build and the Community will be contributing 5.4 million ECU.

NSF gets new director

Almost as soon as John B. Slaughter, the outgoing director of the US National Science Foundation (NSF), the nation's basic research agency, announced that he would leave on 1 November to take up his duties at the University of Maryland, the White House announced his successor. On 3 November Edward A. Knapp assumed his new duties as director.

Knapp, a physicist with degrees from Pomona College and the University of California at Berkeley, had been confirmed in September as assistant director of NSF for mathematical and physical sciences. His entire previous career was with the Los Alamos National Laboratory, where he worked with George A. Keyworth, who is now the President's Science Advisor. Ironically, the White House personnel office made the appointment with despatch while Keyworth, Slaughter and NSF's deputy director Donald Langenberg — who was rumoured as a likely candidate — were out of town.

Knapp's work at Los Alamos began in 1958. He worked on controlled thermonuclear research and helped to plan the linear proton accelerator, the Los Alamos Meson Physics Facility (LAMPF). Knapp spent a year at CERN in Geneva, where he worked out a collaborative programme between CERN and Los Alamos. Before coming to Washington Knapp was director of the laboratory's accelerator technology division.

Since Congress is in recess at present, Knapp is assuming his duties without being formally confirmed. Langenberg plans to stay on, although his name is on a list of candidates for the presidency of the University of New Mexico. At the time that Knapp was appointed, there were rumours in Washington of a major conservative housecleaning at NSF, which could not be confirmed. Moreover, the national elections, which seemed to deprive the Reagan Administration of some of its far-right conservative mandate, make such a sweep very unlikely. **Deborah Shapley**

French energy

Forecasts fall

In the midst of an appalling economic crisis, the French government is about to be struck another blow with the expected publication this week of an official energy forecast which will lower projected electricity consumption in 1990 by nearly a quarter.

The consequences fall neatly on the coal and nuclear industries, both of them political hot potatoes for a socialist government. Coal and nuclear energy are the dominant power sources in France (producing 24 per cent and 37 per cent of delivered electric power in 1981), excepting hydroelectricity (27 per cent) which, as nearly "free" power, is likely to be untouched by the new forecast. The socialist party has committed itself to support the coal industry — and indeed expand production — but the nuclear lobby is strong and supported vociferously by the powerful research and industry minister, Jean-Pierre Chevènement.

The new figures come from the Commission du Plan, an institution which is both within and to some degree aside from the government. But its pronouncements — broad political and economic plans for the future — are taken seriously. In this case, the "long-term energy" committee of the commission has calculated that electricity consumption will not be 450,000 million kWh in 1990 as envisaged in the previous (1980) plan, but only 350,000 million kWh, compared with a true consumption in 1980 of 246,000 million kWh. Thus the projected increase has been halved, with a consequent revolution in thinking about power station construction and power sales.

Electricité de France (EDF), which is strongly behind nuclear power, contests the figures and predicts that consumption will be 390,000 million kWh in 1990; but it still admits that there will be overcapacity. EDF argues that surplus electricity can be exported — French electricity is the cheapest in Europe, largely because of government pricing policy — and that the nuclear power industry must build at least two stations a year until 1990 or it will collapse. A successful nuclear industry will lead to nuclear exports later, the argument goes. But if nuclear power station construction continued at the present rate of four stations a year, it is estimated that coal burning for electricity — which makes up half the French coal market — would fall from its present level of 64,000 million kWh to 32,000 million kWh in 1985 and even less in 1990.

With little union backing for coal (the communist CGT union, which is strong in both the coal and nuclear industry has opted for nuclear energy), and with Chevènement behind nuclear power, it seems likely that the EDF view will be supported, and a substantial nuclear programme maintained, with unpleasant consequences for the socialist party in the French coal districts in the municipal elections in the spring.

Why then are the forecasts falling? The answer is twofold. First, French economic growth is well below target, and seems unlikely to rise before 1985; and second there is growing confidence in the Agency Française pour la Maitrise de l'Energie (AFME), which seems to have had considerable success since its formation earlier this year from a group of disparate bodies concerned with energy conservation and renewable energies.

In 1983, AFME will invest FF1,200 million (£100 million), much of it in investment support grants which will raise a total of FF20,000 million (£1,300 million) in conservation and alternatives next year. The aim is to reach FF40,000 million (£2,600 million) a year by 1990, comparable with the present French investment rate in nuclear power. Some of the seed money is being raised by a tax on petrol at the pump.

By 1990, AFME is expected to have led to renewables usage of some 12 million tonnes of oil equivalent a year (around 10 per cent of primary energy consumption) with the greatest portion coming from wood and biomass, then from low-temperature geothermal heat (particularly by better exploitation of sources in the Paris basin) and finally from solar power. But the great saving comes in energy conservation — around 40 million tonnes of oil equivalent a year by 1990, according to AFME projections, which are broadly accepted by the Commission du Plan.

Robert Walgate

Genetic engineering

Human insulin

Washington

The commercial potential of genetic engineering was boosted in the United States on 29 October when the Food and Drug Administration (FDA) gave marketing approval to Humulin, a human insulin made with genetic engineering techniques. Made by Eli Lilly Company, the substance had won approval for marketing in the United Kingdom only a month before (see *Nature* 23 September, p.293). Although the announcement has symbolic value in the field and in particular for Genentech Inc., the California company that invented it, it will probably not quickly make a material difference to the fortunes of either Genentech or Eli Lilly.

Genetically-engineered human insulin is expected to be almost twice as expensive as the insulins now derived from pigs and cattle, which cost an estimated 26-30 cents per day of treatment. Lilly already has an estimated 85 per cent of the insulin market in the United States, so there is not likely to be a large market for Humulin soon, although the new product has an advantage in the few diabetics who develop an allergy

0028-0836/82/450100-02$01.00

to animal insulins.

The announcement of FDA approval had been so long expected that neither Genentech's nor Lilly's stock jumped much in response, although Lilly's stock, which has been depressed since its sudden withdrawal of the anti-arthritis drug Oraflex earlier this year, traded a little higher after the FDA announcement on Humulin.

FDA gave approval on the basis of safe performance in trials involving about 400 patients a mere five months after Lilly filed its application. The agency also has in the pipeline applications for genetically-engineered products such as human growth hormones and interferons. Approval can take as long as two years, but the agency has recently undertaken a series of controversial moves to shorten approval time and simplify procedures.

Genentech is the first of the highly competitive biotechnology companies with a product approved for human use. The company's task was enormously eased by the security of the support provided by Lilly, which has exclusive licensing rights and which is estimated to have spent $100 million in bringing the product to market. Genentech will receive a royalty on sales which is thought to be in single figures.

Genentech may be following a riskier path in its development of human growth hormone products and gamma interferon. It plans to market these products itself, which explains why it persuaded a group of investors to buy limited partnerships in October, thereby raising $55 million for research. This will support work on a human growth hormone product for children who suffer from dwarfism, but since these are few in number the product would also have to be useful in combating CDSS (constitutionally delayed short stature), a problem that afflicts a greater number of people. Ideally, such a product could also help patients with cachexia, a wasting syndrome.

In addition to the limited partnership, in October four Swedish organizations bought $20 million in Genentech's outstanding shares, or 571,428 shares at $35 per share. (Two weeks later, after the limited partnerships and the FDA announcement, the company's stock reached $50 a share.) The four organizations are Alfa-Laval AB, the Wallenberg Foundation, AB Fannyudde, an investment company affiliated with Volvo, and D. Carengie and Co., another investment company. The president and chief executive officer of Alfa-Laval AB, Harry Faulkner, was made a member of Genentech's board of directors. The company also appointed to its board John T. Potts, chief of the Department of Medicine at the Massachusetts General Hospital. Dr David W. Martin, a professor of medicine and biochemistry at the University of California, San Francisco, has been appointed vice-president for research.

Deborah Shapley

Biotechnology index

Biotechnology index beats Dow

Washington

Nature's third monthly Biotechnology Index set a new high in October, reaching 140.2 from a base of 100 at the end of June. This increase was greater than either the recent increases in the Dow Jones Industrial Index, the leading index of US industrial trading, or the Standard & Poor's 400 index of leading industrial stocks. Thus, the biotechnology companies moved parallel to, but ahead of, the market surge that led the Dow Jones index finally to break through the 1,000 mark in the first week of October.

But the performance of the *Nature* Biotechnology Index may have as much to do with internal factors in the companies themselves as with trends on Wall Street. The "Street" was reacting to continued lowering of inflation and the perception that the US elections, just held, would not upset the direction of the US economy. As one analyst in New York explained, the overall market surge was caused by "institutional money managers getting in who don't want to miss more of the rally". Such managers buy huge blocks of stock and so stay away from smaller companies where such buying would artificially drive up the price.

The analyst went on to suggest that one reason why the *Nature* index did so well was because two companies in the index are large enough to attract some institutional funds and stable enough to ride along with the trend. These are A.B. Fortia of Sweden and Novo Industri A/S of Denmark, which had market capitalizations valued at $751 million and $789 million respectively on 29 October, when the index was calculated. The reasons for the rise in stock price of Genetech are outlined in the preceding story.

The other small companies in the index have also done well lately. "There have been no major flubs in the group", one analyst says. For example, the stock of Cetus, in Berkeley, California, rose after the company announced lay-offs and a re-direction of its research. This was seen as a net gain for the company, because specialists in biotechnology investment had felt that Cetus was over-extended. Hybritech and Damon of Needham have been getting considerable public attention for their work.

Deborah Shapley

Nature **index of biotechnology stocks**

1982 high	1982 low	Company	Close previous month	Close 29 Oct.	Change
45	16⅛	**A.B. Fortia (Sweden)**	34¼	39½*	5¼
8	2	**Bio Logicals (Canada)**	2½	2¼	–¼

17	8	**Monoclonal Antibodies (USA)**	8¼	14¾	6½

The *Nature* Biotechnology Index for October, 1982, stands at **140.2**, compared with **117.9** last month. Base is 100 as of 25 June 1982. Previous indexes appeared in *Nature* 12 August, p.599; 9 September, p.101; and 14 October, p.573. Close-of-month prices are the closing prices on the last Friday of each month. Where stocks are traded over the counter, the price quoted is the bid price. For stocks traded on the American and New York Stock Exchanges, the price quoted is the transaction price. Data from E.F. Hutton, Inc.

*High or low for this calendar year.

In response to readers' comments on the Biotechnology stock index, its composition has this month been changed. Thus Collagen Inc. — a company that does not use new biotechnology — has been replaced by Genex, an important small company which made its first public stock offering after the close of the previous month's index.

This has been done by deleting Collagen's share of the market value of all the companies on 29 October and reallocating that share proportionally among the remaining 14 companies in the index. Then the total market value of Genex shares on that date (an estimated $106 million) was added to the market values of the 14 companies and a new set of market shares calculated. This new set of divisors will be used in the calculation of future indexes.

In response to a further suggestion, there follows information on the trading symbols and, where appropriate, the stock exchanges on which the shares are traded. Most shares are traded over the counter (through brokers). Fortia (FOPHY); Bio Logicals (BIOLF); Bio-Reponse (BIOR); Cetus (CTUS); Collaborative Research (CRIC); Collagen (CGEN); Damon (DMN — NYSE); Enzo-Biochemi (ENZO); Flow General (FGN); Genentech (GENE); Genetic Systems (GENS); Genex (GNEX); Hybritech (HYBR); Molecular Genetics (MOGN); Novo Industri A/S (NVO — NYSE); Monoclonal Antibodies (MABF).

CORRESPONDENCE

Ethics of trials

SIR — The article on the proposed trials of the Medical Research Council (MRC) to investigate supplements in the prevention of neural tube defects (NTD) refers to ethical questions (*Nature* 16 September)[1]. The MRC trial protocol conflicts with the revised Helsinki Code adopted by the 29th World Medical Assembly in Tokyo in 1975[2].

Dr Nicholas Wald is quoted as believing that a trial is ethical if "the likely good of the treatment" balances "the possible harm", implying that harm to one set of patients can be offset by benefit of another set, or of society. The revised code says (paragraph I.5): "Concern for the interests of the subject must always prevail over the interests of science and society". Informed consent does not affect this obligation (paragraphs II.6 and II.4).

The judgement in the Nuremberg trial of doctors for unethical human experimentation in 1947 said: "The protagonists of the practice of human experimentation justify their views on the basis that such experiments yield results for the good of society"[3]. This same judgement enunciated the Nuremberg Code which was replaced by the Helsinki Code of the World Medical Association in 1964, revised in 1975.

Paragraph II.3 of the revised code says: "In any medical study every patient — including those of a control group, if any — should be assured of the best proven diagnostic and therapeutic method". The MRC trial is proposing to supplement a random half of patients with folate regardless of whether they are folate deficient, although techniques for assay of folate status are available and folate deficiency can be remedied in most patients.

Paragraph I.1 requires all research involving human subjects to be preceded by "adequately performed laboratory and animal experimentation". Folate deficiency in animals is reported to cause fetal resorption, low birthweight, small litter size, stillbirths and polymorphic malformations involving all body systems, as would be expected from folate's biochemical role in DNA synthesis. Folate deficiency delays development of the central nervous system in young children and is associated with mental illness in adults[4]. Paragraph I.9 requires subjects of human experimentation to be informed of "potential hazards of the study".

Folate is only one of over 30 nutrients known to be essential for normal embryonic growth. The comparative importance of different nutrient deficiencies in increasing the risk of malformations will only be discovered by extensive biochemical measurement of nutrient status. Randomized trials will never produce the answer if only because trials of 30 different nutrients at only two different levels of supplementation would require 3^{30} trials. It can be argued that the MRC trial, because it will give no information on the prevalence of any nutrient deficiency, contravenes paragraph I.4 of the code which requires "the importance of the objective" to be in proportion to the inherent risk to the individual. The £300,000 would be better spent on well-planned biochemical measurements of the tissues or blood of women who have had babies with neural tube defects or some other malformations.

The MRC trial protocol contravenes paragraph I.12 of the code which says:

> "The research protocol should always contain a statement of the ethical considerations involved and should indicate that the principles enunciated in the present Declaration are complied with."

CAB taxed

SIR — Many eyes must have been rubbed (and job applications drafted) when they read that employees of the Commonwealth Agricultural Bureaux no longer pay income tax (*Nature*, 14 October, p.572), and less self-interested souls must have wondered about the benefit of this to CAB member governments. The benefit lies in what amounts to a 30 per cent cut in taxable salary for CAB employees. A tax consultant works out what employees would normally pay in tax to the UK government, then hands this amount back to CAB. Take-home pay is thus virtually the same as before CAB's internationalization.

ALLAN ROSTRON

Edinburgh, UK

First to use?

SIR — In the article entitled "Vatican and the bomb" (*Nature* 4 November, p.2) you imply that the group convened by the Pontifical Academy in September called for a "declaration of no first use" of nuclear weapons. This is not true.

An earlier draft of the document, prepared by a group of which I was not a member, did indeed "call upon all nations to pledge never to be the first to use nuclear weapons". Many of those present at the final meeting, including myself, objected strongly to this wording on precisely the grounds you state in your article. The words "to pledge" were therefore omitted from this passage in the final document. This was signed by all the participants, and they included all but one of the fourteen who had prepared the earlier draft.

The final version of the document does not contain any suggestion that nations should make a "declaration of no first use" of nuclear weapons.

SIR ANDREW HUXLEY
President of the Royal Society

The Royal Society,

The distinction is important but not, without this explanation, readily apparent.

EDITOR, *Nature*

No to boycott

SIR — In responding to Dr Rowan-Robinson's appeal to end British participation in astronomy in South Africa (*Nature* 14 October, p.574) I must first declare an interest. I was one, if not the first, to propose a unification of observatories in South Africa at a single site at Sutherland and a leading activist in site selection and site testing. I quit British employ in South Africa — with the greatest regret — as Dr Rowan-Robinson would evidently wish others to do, in the expectation that judging by the contemporary official climate I might be deprived of observational opportunities. The establishment of the observatory at Sutherland was a subsequent reversal of policy. Sutherland is a very good site, comparable with those in Chile and superior to those in Australia. Although less well equipped than Siding Spring it offers to the observer relatively long runs at telescopes. Speaking from an experience of 30 years in telescope scheduling, I am certain that these are very often more productive, pound for pound and night for night than short runs on larger telescopes and permit greater flexibility in the choice of programmes. The facilities afforded by the site would be very hard to replace.

As to the question whether British participation condones or encourages apartheid this is more complex than would appear at first sight. Many of the actions of the South African Government are abhorrent to the international community. Boycotts of the type proposed are usually ineffective. Indeed some of the extreme right wing of the Nationalist party might be only too glad to see a diminution of the cultural influence of the English language and traditions. Such a boycott would primarily be a blow to a considerable section of the population who wish to see significant political changes. The South African Government does have a genuine problem of terrorist activity — presumably largely inspired by the Soviet Union which seeks to replace one tyranny by another and to gain control of the crucial oil route round the Cape and the strategic minerals of which southern Africa is the only source available to the free world. It is the hope of all reasonable men that political change will come peacably and that many thousands of innocent and hard working people will not be sacrificed in salving the consciences of those remote from the scene of action.

I believe that the best hope for a peacable solution is to increase rather than decrease cultural links from abroad. In a small way the present influx of scientific visitors promotes this. As to Sutherland itself, it is a dreadful location for the coloured people (there are almost no Bantu in the area) but at the observatory there are six coloured employees with good jobs and good housing. This is not much but it is a positive step towards ameliorating the lot of one section of the population which as far as I could judge from a recent visit is enjoying a period of striking economic advance.

Anatomy of a human cancer gene

A difference of just one nucleotide distinguishes a human cancer gene from its normal counterpart. All of cancer is not that simple but the molecular biologist's approach should be reinforced.

The pages that follow contain an account of one of the most startling discoveries so far in the long and frustrating search for an understanding of cancer. The discovery is startling because it provides an unexpected answer to a question that has been on many people's minds since March last year[1] and certainly since this June[2,3] — what is the difference between a cancer gene and its benign, physiologically indispensable version to be found in normal cells? This week we publish (on pages 143 and 149) two independent but essentially similar answers to this question from two groups in the United States, Dr Robert Weinberg's group centred on the Massachusetts Institute of Technology and Dr Mariano Barbacid's group at the National Cancer Institute. (Further independent confirmation is already in the publication mill.) And on the two following pages, readers will find a cool but enthusiastic appraisal of the significance of these discoveries from Drs Jonothan Logan and John Cairns, of Harvard University.

The essence of what Weinberg, Barbacid and their colleagues have shown is that in cells derived from a bladder carcinoma, there is a gene which differs from the naturally occurring gene in the simplest possible way — the replacement of one specific nucleotide in the DNA by another. The consequence is that the protein whose assembly is governed by the gene differs from the normally manufactured protein again in the simplest possible way — the twelfth amino acid (measured from the end of the protein molecule carrying a free amino group) is changed; in the bladder carcinoma cells studied, the normal glycine is replaced by valine. Nothing could be simpler.

So why the surprise? The most obvious explanation is that this simple result fits oddly with the opinion that has grown up in the past several years that because most kinds of cancer appear to involve cells that have somehow escaped from the unknown constraints that normally limit the multiplication of differentiated tissues, genetic explanations of cancer would probably turn on some property of the mechanisms by which the activity of various genes is controlled. Indeed, Weinberg and his associates describe how, in their study of what are known as the EJ bladder cancer cells, they first looked for differences from the normal in the region outside the gene proper where controlling elements are usually found. They found none of significance. Their account of how they turned to look for differences within the part of the gene which regulates (through the intermediary of messenger RNA molecules) the assembly of amino acid units into protein molecules is as nice an illustration as there could be of how logic can triumph over incredulity.

Several questions now arise, not the least of which is how such a small difference in the structure of a protein molecule can be responsible for such profound physiological differences in the characteristics of a cell, its conversion from a normal to a malignant cell. The fact that the protein concerned is known only as p21 is to be taken as a sign that little more is known about it than that it has a molecular weight of 21,000. The protein appears to be an enzyme and appears bound to the inner surfaces of plasma membranes (so that the production of an abnormal protein would not be apparent from the outside of a cell even if the abnormality were much more pronounced than that now found). Both the groups now reporting draw attention to the way in which a single amino acid substitution could nevertheless have a profound effect on the activity of an enzyme — Barbacid and his colleagues have used computer techniques to show that the replacement of the small glycine unit by the much larger valine could have the effect of stiffening the end of the molecule, perhaps profoundly changing its catalytic properties in the process. However this may be, one thing is certain — there will now be mounted a determined effort to throw light on the normal function of the p21 protein, and of the other proteins it may influence. That will be a gigantic undertaking.

Even at this stage, however, it is clear that the discovery now reported is not a universal explanation of cancer. Thus Barbacid and his colleagues point to the apparent contradiction between their discovery and the demonstration earlier this year[2] that it is possible to make normal cells cancerous simply by infecting them with DNA corresponding to the normal p21 gene to which has been attached pieces of viral DNA corresponding to those thought to be necessary for the functioning of the tumour viruses known as retroviruses. The result of that procedure is to increase the amounts of p21 produced, which suggests that the amount of the protein generated is also relevant. A little abnormal p21, or a lot of the normal product, seems to have similar consequences for a cell, but for reasons not yet properly understood. And why should there be such a close relationship between the cancer genes now described and the retroviruses? Logan and Cairns point in what follows to the fascinating questions raised by that train of speculation.

So where will it all end? Logan and Cairns rightly point out that the discoveries now reported cannot conceivably amount to an explanation of the general phenomenon of cancer. For decades, it has been all too clear that both the causation and the course of different kinds of cancers are exceedingly varied. The importance of what has now been done is that it points unambiguously to one feature of the biochemical apparatus of the vertebrate cell whose abnormality must be supposed to be critical for the development of malignancy. Inevitably there will now be a hunt for a similar analysis of the other known cancer genes, close on a dozen of which are known.It is in the literal sense marvellous that the techniques of genetic manipulation developed in the past decade should now be used to such good and delicate effect (which is in no sense to belittle the difficulty of what has been accomplished, as a reading of the two articles, each with its interlocking network of individual experiments, will quickly show).

What has happened, as Logan and Cairns point out, is certain to change the way in which cancer research is planned. In recent decades, there has been recurrent tension between those (like Cairns himself[4]) who argue that the prime objective should be to understand the phenomenon of malignancy and those who hold that the problem is so complicated that it would be better to concentrate on identifying the causes of concer — and then to avoid them. Nobody will now pretend that understanding is so close at hand that more empirical ways of avoiding cancer or tackling the consequences can be abandoned, but there is the strongest case for seeing that the huge sums of money available for research on cancer are redirected in the directions to which these new discoveries point, and that they are not exclusively spent by the large laboratories but, rather, by those groups of workers whose flair and versatility seem finally to have put paid to the old slur that molecular biology has done nothing for patients.

The secrets of cancer

from Jonothan Logan and John Cairns

THIS year may one day be seen as the year when a strong sense of order came to cancer research and the long drive to understand the cancer cell really got under way. To appreciate the significance of papers like the ones appearing in this issue (Tabin *et al.* p.143 and Reddy *et al.*, p.149) we have to look back at some recent history.

Molecular genetics has brought to biology a new level of order and understanding. The informational macromolecules have been identified and we can now trace at least some of the simpler programmes in metabolism back to their source in the logical circuitry of DNA. What made this possible, more than anything else, was the discovery that genes could be transferred from one cell to another. Without bacterial transformation and the special transfer of information that occurs during virus infection, it would have been hard to show that genes are made of DNA. Without bacterial mating and transduction, dissection of the operon and its component parts would have been almost impossible. Given the wisdom of hindsight, we can see that even the most detailed catalogue of the changes that occur when *Escherichia coli* is fed lactose could not, by itself, have told us how cells regulate protein synthesis. Fortunately, the constraints imposed by evolution require genes to be capable of functioning in almost any context. In the bacterial cytoplasm, everything can interact with everything else, and trying to analyse it is like trying to understand the economy. In the genome, however, genes battle it out one by one, although they are of course being judged by their effects upon the cytoplasm. It is this wonderful separation of living systems into one arena of great complexity and another of great simplicity that has made it possible to find out how cells know what they ought to be doing.

This message has not yet had its full impact on cancer research. A glance at the current journals will show how many people are still trying to understand the biology of cancer by making inventories of the properties of the cells present at each stage of carcinogenesis. Of course, the transition has been difficult. To anyone accustomed to the delights of bacterial genetics, the vertebrate cell must seem an impenetrable forest, with its vast genome, poorly understood systems for gene regulation and — most important of all — its relative inaccessibility to the techniques of genetics. Nature, however, provided one avenue of approach, the tumour viruses. Despite the slender means at their disposal (a few genes-worth of nucleic acid) they possess the means to make a cancer. This fact alone tells us that the various systems of control in animal cells come together at certain focal points ('nodes' in computer terminology) where they can be subverted by single genes and their unique gene products. As we shall see later, evidence is now emerging that these focal points can be the site of attack for at least two other completely distinct forms of carcinogenesis.

Until recently, the vast size of the mammalian genome effectively prevented any direct search for the cellular genes involved in cancer. Without some selective procedure, searching for a mammalian gene is equivalent to looking, without an index, for an article of this length (2,000 words or 20,000 characters) that is known to have appeared in *Nature* some time since 1900 (that is, somewhere in a text of 3×10^9 characters). The genes were discovered, however, because they confer tumorigenicity when they are picked up by certain retroviruses: the virus was therefore doing the selection and the purification. The genes have come to be called 'oncogenes' as if their primary role were to cause cancer. But it was soon realized that typically they are cellular genes ('proto-oncogenes'), whose function is sufficiently important for them to have been highly conserved over the long period of evolution of the vertebrates. One of them is known to change its level of expression during embryogenesis and so it may be a gene normally concerned with development. Another has been shown to code for a protein kinase capable, in principle at least, of modulating the properties of many different gene products, which is just the sort of operation we might expect to find at a focal point in the regulatory circuits of the cytoplasm. But the function of most of the dozen or so identified oncogenes is not yet known. Presumably, each oncogene is not equally important in every tissue and therefore will be more often involved in some kinds of cancer than in others.

The tumorigenic retroviruses can cause cancer in at least two different ways. The virus can bring in an oncogene which, because it is under the control of the viral promoter of transcription, is inevitably transcribed at too high a level. Alternatively, the virus need not contain an oncogene, but merely provide a strong promoter which, by chance, can then become integrated next to one of the cell's oncogenes; this is a much less efficient form of tumorigenesis and usually succeeds only after a long time interval. To summarize, the product of each cellular proto-oncogene seems to be capable of making a cell into a cancer provided that it is produced to excess or has undergone a change in amino acid sequence.

Because the retroviruses are so adept at picking up, transporting and reintegrating cellular genes, they have drawn attention to the particular genes that can endow them with tumorigenicity. It could therefore have been argued, at least until recently, that none of this has much to do with human cancer which, as far as we know, is seldom brought on by an RNA retrovirus. In the past ten years, however, a completely different way has been found for studying the genes involved in cancer. Certain cell lines (most notably the NIH line of 3T3 mouse fibroblasts) have been found to be capable of taking up raw DNA and to be transformed to permanent tumorigenicity if the incoming DNA has been derived from animal, or human, tumours or tumorigenic cell lines. Since human DNA contains certain telltale sequences, not found in mouse DNA, it has been possible (given the formidable armoury of restriction enzymes and all the other paraphernalia of genetic engineering) to isolate these human genes that are tumorigenic for NIH 3T3 cells and presumably were at least partly responsible for the cancers from which they were derived. The fact that such experiments are possible is, in itself, a dramatic demonstration that alteration of the genome is an essential step in the production of some cancers. At this point, it is simplest to list the other major conclusions to have come from these studies of 'transfection'.

First, it is just possible, with great difficulty, to transform NIH 3T3 cells by feeding them their own DNA, provided that it has been fragmented into roughly gene-size pieces; but these transformed cells are then an efficient source of transforming DNA, provided that it is not highly fragmented. By analogy with the retroviruses, it seems likely that the first, and difficult, step is to bring one of the cell's proto-oncogenes under the control of one of the cell's strong promoters, but once these have been brought together they can easily transform other cells, provided that they are not separated.

Seond, when efficiently transforming DNA arises in naturally occurring tumours, or is found in retroviruses, it can function across species barriers; for example, human tumour DNA can transform mouse cells. This is what we might expect, since the oncogenic sequences have been so closely conserved during evolution.

Third, in several instances, the tumorigenicity of DNA from human tumours has been traced to the activation of one of the oncogenes that had been identified in murine sarcomas (either the Harvey or the Kirsten *ras*), suggesting that a change in the function of either of these can be a step in the formation of cancer in several organs. Interestingly, in the examples studied in this issue of *Nature*, the tumorigenicity of DNA seems to be

---

Jonothan Logan and John Cairns are in the Department of Microbiology, Harvard School of Public Health, Boston, MA.

0028-0836/82/450104-02$01.00

due, not to a change in level of expression of the oncogene, but to a change in its coding sequence; this suggests that the cancer may have resulted, in part, from exposure to the kind of mutagen that can produce this particular change, a GC to TA transversion.

We may be seeing here the shape of things to come. Even if mutation of the oncogene was not actually one of the rate-limiting steps in that particular patient's progression to bladder cancer, it does seem that the requisite technology is fast approaching that will make it practicable to search through selected regions of the genome for every kind of textual aberration. One spectacular example of this is about to be reported elsewhere (P. Leder, personal communication). Most B-cell lymphomas bear a translocation of the end of chromosome 8 into the region of one of the chromosomes concerned with antibody synthesis (chromosomes 2, 14 or 22). It has now been possible to isolate the region of DNA involved in this rearrangement and show that it contains the proto-oncogene called *myc*, that was originally found in association with a chicken leukaemia and, in humans, is located on chromosome 8. So here too is another human cancer arising apparently as the result of activation of an oncogene, in this case because the gene has become caught up in the active chromosomal region involved in antibody synthesis.

We seem, therefore, to be at one of those wonderful moments in science when many lines of research come together and much that was impossibly obscure suddenly seems plain. There are, however, one or two caveats that are well known to everyone engaged in this work but may not be immediately obvious to outsiders.

Natural carcinogenesis is a multistep process. Evidence for this comes from epidemiology (for example, the relation between incidence of lung cancer and the frequency and duration of cigarette smoking) and from laboratory experiments, and shows that the formation of a cancer requires several independent, rate-limiting steps. Thus, the provision of an active oncogene, whether by activation of a cellular gene through rearrangement or mutation or by viral infection, presumably corresponds to only one of a sequence of steps. Given that cancer arises from a sequence of steps, we would expect the first steps to be the ones that allow clonal expansion and free competition between cells, because this should then make all the other steps occur more efficiently and allow continuous selection of faster growing cells. But special provisions appear to have been made to prevent competition between individual cells in intact tissues. So a significant component of carcinogenesis in whole animals must be the production of whatever changes are needed in order to allow competition. If, for example, the first step in carcinogenesis has to be the liberation of cells from control by cell–cell interaction, we could not find this out by studying the transformation of cell lines which have, of course, already taken this step.

Transfection experiments with NIH 3T3 cells are open to other objections. Mice will develop cancer at the site of implanted plastic sheets, and it may be for this reason that their cells can readily be induced to grow profusely in tissue culture dishes. Guinea pigs (and probably humans) are not susceptible to such foreign body carcinogenesis, and their cells do not readily form immortalized cell lines. We could argue that the 3T3 cell is already part-way to becoming a cancer cell, and for that reason may not provide the right assay for certain kinds of tumorigenic DNA.

In transfection experiments only about one in a million cells acquire and express the exogenous DNA. This may mean that only cells already possessing a special genetic or metabolic alteration are competent to acquire foreign DNA. Such cells could be just those that have taken one of the rate-limiting steps towards cancer; if transfectibility is evidence of a step towards transformability then this step cannot be elucidated in these experiments. (Although transformation by viruses is very efficient, the viral reverse transcriptase could conceivably be making gene rearrangements much more frequent and, in that way, be by-passing what is normally a rate-limiting step.)

Most tumours studied so far, whether occurring naturally in humans or produced by X rays and chemicals in animals, do not yield DNA that is oncogenic in cell transfection experiments. So the assay, as presently constituted, is not detecting the genetic events responsible for many types of cancer. It is important to remember that transfection can only pick up changes that, in the genetic sense, are dominant; also it will only detect oncogenes which provide products that these particular recipient cells require for transformation (for example, the *myc* gene is not efficient at transforming NIH 3T3 cells); lastly, there is the requirement in these experiments (and in tumorigenesis by viruses) that the transforming genes are not too large to be transferred intact.

Above all, we need to keep in mind that natural human carcinogenesis is a multistep process. We do not know what the rate-limiting steps are, nor which of them are most sensitive to environmental influences and therefore a proper object for preventative strategies. But we can at least feel that the technology for studying genes and their patterns of expression are now advancing so fast that the molecular biologist will soon be telling the epidemiologist what to look for. ☐

THE PROJECTION PRAXINOSCOPE

M. Gaston Tissandier describes in *La Nature* an ingenious adaptation of the praxinoscope, under the above name, by means of which the images are projected on a screen, and are visible to a large assembly. Our engraving will give an idea of the arrangement and the effect produced. By a modification of the "lampascope", M. Reynaud, the inventor, obtains by means of an ordinary lamp, at once the projection of the scene or background — by the object-glass which is seen at the side of the lantern — and of the subject, by another object-glass which is shown in front of and a little above the same lantern. For this, the positions of phases which form a subject are drawn and coloured on glass, and are connected in a continuous band by means of any suitable material. One of these flexible bands is placed in the wide crown of the praxinoscope, which is pierced with openings corresponding to the phases of the subject. A hand-lever on the foot of the instrument allows a moderate and regular rotation to be communicated.

The Nobel prize in physics

from Norman Dombey

THE award of the Nobel prize in physics to Ken Wilson of Cornell University honours the first of a new generation of theoretical physicists who are as familiar with the physics of thermodynamic phase transitions or the first second of existence of the Universe as they are with electron–proton scattering. This trend marks a welcome return to the spirit of the 1920s and 1930s, when the pioneers of quantum mechanics were equally at home with crystal lattices, molecules, atoms and the recently discovered nuclei. Wilson is not the only theorist to have noticed similarities between the theoretical analysis of renormalization in relativistic quantum field theory (which describes the behaviour of elementary particles) with the then unsolved classical problem of the universality of the critical indices of phase transitions between differently ordered macroscopic states of a system (such as the liquid–gas transition), but no other physicist has had the insight and stamina necessary to see the work through and to develop a general method for the calculation of critical indices.

A ferromagnet is a good example to illustrate universality. In ferromagnets, spontaneous magnetization occurs — magnetization persists in the absence of an external magnetic field, provided that the temperature is less than some critical temperature T_c. It is found experimentally that magnetization goes to zero as the temperature T tends to T_c as a power β of $(T-T_c)$. β for all ferromagnets has a value between 0.3 and 0.4. Similarly, other quantities, such as magnetic susceptibility, vary near T_c as a power γ of $1/(T-T_c)$ and experimentally $\gamma = 1.2$–1.4. Although the Ising model of a ferromagnet (see *News & Views* **299**, 675) was solved by Onsager in two dimensions to show that a phase transition exists, and can be solved numerically in three dimensions to give critical indices in reasonable agreement with experiment, it does not provide any explanation of the universality of behaviour near the critical temperature (which itself varies widely between ferromagnets).

The problem of universality can be phrased as follows: starting with an energy function describing the microscopic properties of the system of interest and containing the physical parameters of the system, for example the spin–spin interaction between neighbouring lattice sites, is it possible for the equilibrium state near the critical temperature to be independent of the initial parameters? If so, then the critical indices will depend only on the gross features of the initial energy function, such as whether the physical variable involved is a scalar or vector quantity and whether the underlying space is two- or three-dimensional. Kadanoff[2] had shown that spin-blocking (the pairing and re-pairing of spins on the lattice) provided a recursive set of transformations which could in principle take the initial energy function into the form desired.

There is an analogous result in relativistic quantum field theory. The initial parameters in the Lagrangian (the appropriate relativistic energy function) are not the measured physical parameters. This is because infinities occur in the calculational procedures and in order to remove these infinities a process of renormalization is carried out whereby the infinities are subtracted out at some arbitrary momentum Λ. Hence the physical parameters of the theory, for example charge and mass, are functions of the initial parameters and Λ, but the results of any calculation must only depend on the physical parameters and not on Λ. So a change of scale whereby Λ is replaced by 2Λ should not have any influence on the result of a calculation. Gell-Mann and Low[3] in 1954 wrote down the mathematical conditions necessary for this invariance and these are known as the renormalization group (RG) equations of the theory. Certain scaling laws among the field quantities and momenta of the theory follow from the RG equations. This is the problem that Wilson studied further throughout the 1960s.

Wilson is most remarkable in that during this period he was not at all interested in publishing papers. He received his PhD from Caltech in 1961 with a thesis[4] on a problem in quantum field theory where a relativistic pion field interacts with a static nucleon. This problem is complex enough to be interesting while tractable enough for the RG equations and scaling laws to be worked out. He did not publish the thesis and he only published one paper[5] on his progress on this problem until he obtained his main results which were published in a series of papers[6] beginning in 1969; the simplified model of his thesis played a major part in the derivation of his results. These results, very approximately, show that in a renormalizable theory at sufficiently high momenta when all masses in the theory can be neglected and therefore no basic momentum (or length) scale exists, the limiting form of the physical amplitudes are given in terms of numbers called the anomalous dimensions of the theory which are calculable using the RG equations.

Michael Fisher, who had worked for many years on the numerical calculation of critical indices, went to Cornell in 1966 from King's College, London and Wilson's awareness of the problem of universality probably stems from his presence. But it also stemmed from the field theory calculations of the fixed nucleon model in that in order to make progress with his integral equations, Wilson had split up the space-time continuum into cells, thereby giving it a lattice structure. Reversing this process, so that a continuum field theory limit could be taken starting from the crystal lattice of a ferromagnet, was a natural development.

In the region of a phase transition the correlation length in a material becomes arbitrarily large, so again there is no basic length scale. It did not take Wilson long to convert the Ising model into field theory and to look for the RG equations of the theory, albeit now in three dimensions rather than the four of relativistic field theory. For the phase transition he had to work in the low-momentum limit (long-wavelength) of the RG equations whereas in particle physics the high-momentum (short-wavelength) limit pertains. Nevertheless, anomalous dimensions were translated into critical indices and he was able in 1971 to publish a calculation of γ for the three-dimensional Ising model using the RG equations[7]. Techniques for the calculation of critical indices via the RG equations soon improved, largely due to a trick invented by Wilson and Fisher[8], and it became apparent that universality did indeed follow from the RG equations[9] since the initial parameters in the energy function were irrelevant near the phase transition.

Perhaps the most interesting lesson to be drawn from Wilson's career is that difficult problems in science deserve long study (otherwise they would not be difficult) and that solutions may well lie in methods developed in a different area of science. So extreme specialization (such as that of graduate students) and the compartmentalization beloved of bureaucrats (for example, in Britain ferromagnetism is dealt with by the Science Board of SERC while particle theory comes under the Nuclear Physics Board) may not be helpful. Another lesson is for tenure committees and for those social scientists who aim to measure successful science: it is not good enough to weigh publications or count citations. Truly original work is unlikely to

be produced on a production line. Finally, on a hobby-horse of my own, universality, where it exists in physics, is a concept based on real experimental results, unlike the present theoretical chimaera of unification for which there is as yet no hard experimental evidence (see *Nature* 279, 675; 1979). ☐

The biology of teratocarcinomas

from P.N. Goodfellow and P.W. Andrews

THE early development of mammals is one of the major areas of biology not yet fully susceptible to the techniques of molecular biology. The chief obstacle is that the very fact of development makes it difficult to obtain enough cells, at the same stage of development, for molecular and biochemical analysis. Teratocarcinomas and their stem cells (embryonal carcinoma or EC cells) offer a solution, for these embryonic tumours display extensive cellular differentiation, often into derivatives of all three germ layers as well as the extraembryonic tissues. EC cells can be cloned and maintained *in vitro* as undifferentiated cell lines and differentiation can then be induced by altering the growth conditions, transplanting the cells into mice or by chemical inducers. Seven years ago a meeting on the biology of teratocarcinomas was held at Nutley, New Jersey[1] and progress since then was debated at a recent conference* held at Cold Spring Harbor.

Complex systems involving cellular interaction and the generation of diverse cell types can only be studied if the various cells in the system can be distinguished and if the changes in cellular phenotype are under the control of the investigator. Traditionally, morphology has served as the primary indicator of differentiation, but its assessment is subjective and it can be misleading. However, the number of biochemical and immunological markers of cellular differentiation in EC cells is rapidly expanding. These include cell surface antigens (for example, the EC marker, SSEA-1)[2], α-fetoprotein[3], alkaline phosphates[4], plasminogen activator[5], the various cytoskeletal elements (R. Oshima, La Jolla Cancer Research Foundation; R. Kemler, Friedrich-Myescher-Laboratorium der Max-Plancke Gesellschaft) and basement membrane components (C. Howe, Wistar Institute; B. Hogan, ICRF). Chemical inducers, such as retinoic acid, dibutyryl cyclic AMP and dimethylsulphoxide, permit induction of differentiation along pathways which are apparently specific for the inducer and the particular EC cell line used (M. McBurney, University of Ottawa; M. Damon, Pasteur Institute). The mechanisms by which these substances cause their effects is not known, although for retinoic acid there is an intracellular receptor, which appears to mediate the action of this agent (M. Sherman, Roche Institute of Molecular Biology, Nutley). Differentiation in culture seems also to be affected by cell contact[6,7], by growth factors produced both by stem cells (L. Gudas, Sydney Farber Cancer Institute) and by differentiated derivatives (C.M. Isacke, University of Oxford), and by interaction with extracellular matrices composed of basement membrane components such as laminin, fibronectin and type IV collagen. For example, organization of a laminin-containing basement membrane in embryoid bodies produced by suspension cultures of EC cells seems to be an important prerequisite for the outer cells to complete their differentiation to α-fetoprotein-secreting visceral endoderm-like cells (E. Adamson, La Jolla Cancer Research Foundation).

While definition of the ways EC cells differentiate in culture represents a first step, eventually it will become important to study the changes that occur at the molecular level. However, cloned DNA probes for genes regulated in early development are still a rarity. Those which are available suggest that regulation occurs, at least in part, at the level of transcription, as for the *H-2D,K* genes of the mouse histocompatibility system (G. Gachelin, Pasteur Institute). The cloning of further developmentally regulated genes is clearly a priority, and several groups are actively pursuing this area (K. Marotti, Rockefeller University; B. Hogan; C. Howe).

In the meantime, viruses remain valuable probes of cellular differentiation. Although mouse EC cells will not support expression of small tumour viruses such as polyoma or the C-type retroviruses, they can be infected by polyoma mutants which appear to be related by having suffered sequence rearrangements and mutations in the early promoter region (in the *Pvu*II-4 fragment[8]) (M. Vasseur, Pasteur Institute; E. Linney, La Jolla Cancer Research Foundation; J. Lehman, University of Colorado). The relationship between the sequence alterations and EC differentiation, however, is not clear, especially as the mutants grow normally on mouse fibroblasts. New mutants have also been isolated which are capable of infecting cell lines isolated from mid-term mouse placenta, these mutants also grow in 3T3 but cannot grow in EC cells (K. Tanaka, National Cancer Institute). At least some of the EC selected mutants can grow in the placenta-derived lines. Before these results can be ascribed to specific developmental changes it is necessary to know what cells, if any, in the adult are refractory to polyoma infection. The block to retrovirus expression is also poorly understood. The simplest explanation is that expression of virus introduced into EC or early embryonic cells (C. Stewart and R. Jaenisch, University of Hamburg) is prevented by methylation — other mechanisms must also be involved, though, for inhibition can occur before full methylation is detected (J. Gautsch, Research Institute of Scripps Clinic).

One of the exciting recent findings in molecular biology is the observation that the transforming genes of many oncornaviruses have equivalents in normal cells[9]. The possibility therefore arises that they may be genes that are important for regulating the growth of specific cell types, and may themselves be developmentally regulated. Many cellular oncogenes are indeed expressed differentially in development and several are expressed in EC cell lines (R. Muller, Salk Institute). Some of the cellular oncogenes (or at least their viral equivalents) are protein kinases which phosphorylate tyrosine[1]. It is thus interesting that several phosphotyrosine-containing proteins can be identified in early stage mouse embryos and EC cell lines and changes in them can be observed (C. Carlin, Wistar Institute).

Probably one of the most important technical innovations to be discussed at the conference was the recent discovery of a technique of deriving pluripotent EC cell lines from embryos explanted *in vitro* (E. Robertson, University of Cambridge; G. Martin, UCSF). At the earlier Nutley

meeting one of the observations reported was the ability of EC cells, transplanted into a blastocyst, to participate in normal embryonic development, leading to a chimaeric mouse with tissues derived from both the host blastocyst and the EC cell[11–13]. However, the efficiency of chimaerism with most EC cell lines is low; this may be a result of small chromosomal abnormalities of many EC cells after prolonged *in vitro* culture, although other factors may be involved since some apparently euploid lines also fail to form chimaeras (J. Rossant and M. McBurney, Brock University, Ontario). Since the embryo-derived EC cells seem to have less chromosomal abnormalities, at least in early passage, the hope is that these may produce much higher rates of chimaerism.

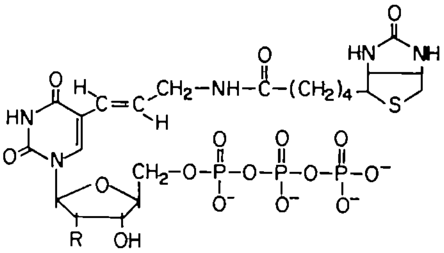
The other important possibility stemming from this technical advance is that of readily introducing known embryonic mutant genes into EC lines *in vitro*. For example, embryos homozygous for mutants of the *T/t* complex die at various stages of development. The mechanism of action of these lethal genes remains obscure, but suggestions varying from the aberrant expression of cell-surface molecules important in critical cell interactions to general metabolic deficiencies have been proposed. An embryo-derived EC cell line, homozygous for t^{w5}, which causes embryonic death at about day 8 of development, has been isolated (T. Magnusson, UCSF). However, this t^{w5}/t^{w5} EC cell line grows normally *in vitro* and forms well differentiated tumours when injected into mice. These observations suggest that embyronic lethality caused by this mutant is due to inability to organize embryonic structures at the proper time, rather than an inability simply to grow and differentiate. □

Lighting up time

from Sue Malcolm

THE report from David Ward's laboratory at Yale University School of Medicine of a new method for detecting specific DNA sequences suggests that a considerable increase in both sensitivity of detection and resolution may be just round the corner. The technique may be particularly valuable in the antenatal detection of those hereditary diseases where the molecular and chromosomal mapping of the genes involved has already been made possible. The basic idea is to incorporate a biotin-labelled nucleotide into the nucleic acid probe, to bind the substituted nucleic acid with an anti-biotin antibody (raised in rabbit) and then detect the complex either by fluorescence with a second antibody (goat anti-rabbit) coupled to fluorescein or cytochemically with the second antibody coupled to an enzyme such as horseradish peroxidase.

Present techniques rely on radiolabelling cloned DNA fragments with ^{32}P- or ^{125}I-labelled nucleotides. After hybridization, the labelled sequences can be detected with great sensitivity, but there are a number of limitations to the use of the isotopes. ^{32}P has a half-life of only two weeks and probes must be made and used immediately. This presents particular difficulties for laboratories any distance from the major suppliers (such as clinical laboratories in many of the countries where antenatal diagnosis of the haemoglobinopathies is desirable), and the handling and disposal of the radio-isotopes presents a health hazard, not to mention a bureaucratic hazard. The high energy of the radioactive emissions, particularly of ^{32}P, makes the grains on the film too scattered to give useful resolution in detecting specific mRNA sequences in individual cells, or genes on chromosomes. Tritiated nucleotides give much better resolution in cytological specimens but are necessarily also of lower specific activity, and the amount of nucleic acid corresponding to a single-copy gene on an individual chromosome or a low-abundance mRNA in a single cell is so low that their detection only becomes possible with the use of very long autoradiographic exposure times or the pooling of data.



1, R = OH
2, R = H

Biotin-labelled derivatives of UTP (1) and dUTP (2). In 1, R = OH and in 2, R = H.

The new technique makes use of biotin-labelled derivatives of dUTP and UTP (see the figure) synthesized via 5-mercurated intermediates (Langer, Waldrop & Ward *Proc. natn. Acad. Sci. U.S.A.* **78**, 6633; 1981). Other nucleotides could be synthesized by the same method but dUTP and UTP have proved the easiest to make. The Bio derivatives can be introduced easily into RNA and DNA. Bio-dUTP is a good substrate for the enzymes DNA polymerase I of *Escherichia coli* and bacteriophage T4 DNA polymerase and can be incorporated efficiently into DNA by 'nick-translation'. Bio-UTP can be incorporated into cRNA by *E. coli* RNA polymerase. Unfortunately, the analogues do not seem to function as substrates for avian myeloblastosis virus reverse transcriptase or for eukaryotic RNA polymerases.

In hybridization, Bio-substituted nucleic acids behave similarly to the non-substituted versions. There is no change in the melting temperature of DNA containing 20 biotin molecules per kilobase introduced by nick translation. Viral DNA in which all the thymidines in one strand are replaced by Bio-dUMP shows a drop in melting temperature of only 5°C. Lightly substituted DNA (5.5 per cent of thymidine substituted by Bio-dUMP) hybridizes in solution at the same rate as non-substituted DNA. The substitution may have some useful side effects — the hydrophobic side chain added to the DNA changes its physical properties and, for example, results in it being extracted into the phenol phase during phenol extraction. This could cut down background during hybridization on either nitrocellulose filters or on glass-mounted cytological preparations.

Langer-Safer and colleagues (Langer-Safer, Levine & Ward *Proc. natn. Acad. Sci. U.S.A.* **79**, 4381; 1982) have now used the biotin-labelled DNA to detect specific sequences in *Drosophila* polytene chromosomes by *in situ* hybridization. Here there are no problems of detection as the DNA in the polytene chromosomes is replicated many times. The probes were prepared with between 8 per cent and 40 per cent of their thymidine residues substituted with Bio-dUMP, and after hybridization to the chromosomes they were reacted with rabbit anti-biotin antibody. For direct fluorescence detection the slides were incubated with goat anti-rabbit antibody labelled with fluorescein and examined by phase-contrast and fluorescence microscopy. There are a few disadvantages to this method, in particular bleaching of the fluorescent signal under the light source, so a second method, using a histochemical stain, was also employed. The slides were incubated with horseradish peroxidase-conjugated sheep anti-rabbit IgG and the peroxidase activity then used to convert the substrate diaminobenzidine into an insoluble brown precipitate which can be clearly distinguished in Giemsa-stained preparations. One valuable aspect of this method is that the length of chemical exposure can be continuously monitored to give an optimal reaction time. The same method has been used by Manuelidis to detect repeated sequences in human chromosomes and mouse satellite sequences in mouse chromosomes [in *Genome Evolution* (eds Dover, G.A. &

Sue Malcolm is in the Department of Biochemistry, Queen Elizabeth College, Campden Hill Road, London W8.

0028-0836/82/450108-02$01 00

Flavell, R.B.) 263, Academic, New York; 1982].

The method has many potential variations, the most obvious being the use of avidin-bound enzyme complexes (to exploit the biotin/avidin K_d of 10^{-15}) or the use of biotin derivatives with longer linker arms (to increase accessibility). In fact a derivative, Bio II-dUTP, with an extra seven atoms in the linker arm, is already commercially available. The day may not be far removed when you carry your Southern blot filters to lunch with you and check their progress every now and again. □

More to melanism than meets the eye

from J.S. Jones

INDUSTRIAL melanism is the textbook example of natural selection in action. Like most such examples it is usually presented in a way which is both incomplete and inaccurate. The popular view is that a mutation to a black form appeared in the previously light-coloured populations of the peppered moth *Biston betularia* at the beginning of the Industrial Revolution. As in a sooty environment the melanics were well concealed from predators they replaced non-melanics in polluted cities while remaining at a low frequency in the countryside. The real story is, however, much more complex and a recent computer model, produced by G.S. Mani, a University of Manchester physicist, shows that selective predation, differences in fitness unrelated to crypsis and gene flow must all be taken into account before many puzzling features of melanism can be explained.

Melanism has always presented a number of problems. It appeared in industrial Britain not only in *Biston* and more than a hundred other moths, but in species not subject to intensive predation such as beetles, cats and birds[1]. In ladybirds, melanics became more common mainly because the increased efficiency of absorption of solar energy gives them an advantage in the smoky atmosphere of cities[2]. Melanic pigeons are favoured in towns because the associated hormonal changes make them better able to exploit the possibilities for winter breeding presented by the year-round availability of food[3]. In both these distantly related organisms, the mating advantage of melanic males over typicals may also be important in their evolution[4]. Although in the peppered moth the first melanic was not recorded until 1848 in Manchester, dark forms of other moths were common in forests long before the industrial revolution, and in the newly polluted cities of north-east America, industrial melanism evolved exceptionally rapidly as these variants spread from the forests. Even the apparently simple case of industrial melanism in *B. betularia* involves at least four alleles, and many British populations contain three phenotypically distinguishable classes — the pale form *typica*, the intermediate *insularia* and the full melanic *carbonaria*[1,5].

There are several puzzling aspects of melanism in *Biston*. Even in the most polluted areas, such as central Manchester, the frequency of melanics never rose above 95 per cent, although field experiments on marked individuals show that melanics are considerably better camouflaged and should have replaced lighter forms long ago if only differential predation is involved[6]. When pollution was reduced the frequency of *carbonaria* fell rapidly (from 95 per cent to 82 per cent between 1960 and 1975 near Liverpool) although the melanics still appeared better camouflaged than typicals. In addition, melanic alleles in *B. betularia* reach a frequency of 80 per cent in rural East Anglia, where there is little industrial pollution[7]. None of these observations can be explained by simple directional selection by predators.

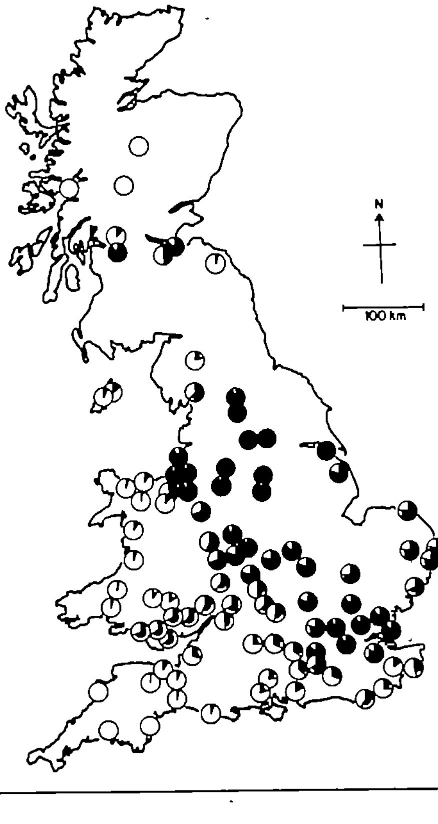


Fig. 1 Distribution of melanics in *Biston betularia*. White sector: *typica*; black sector: *carbonaria*; halved sector: *insularia* (from ref. 1).

Some of the apparent anomalies in the distribution of melanic *B. betularia* are related to its powers of migration. Males migrate about 2.5 km per generation, and this results in considerable gene flow between polluted and unpolluted places[8]. Computer simulations show that a balance between selection and migration is enough to explain the persistence of typicals in highly polluted areas[6], and partly explains why the rapid decrease in melanic frequency does not coincide with the urban boundaries of Liverpool and Manchester. However, gene flow alone cannot explain the position of this cline, nor why melanics are so common in some unpolluted parts of Britain[9].

Mani's model incorporates new information on fitness differences between melanics and typicals which are unrelated to visual selection by predators[10]. Breeding experiments involving 12,569 larvae from 83 families show such that differences are quite considerable; for example, *typica* homozygotes are at an approximately 30 per cent disadvantage to *carbonaria* homozygotes and a 7 per cent disadvantage to *insularia* homozygotes when raised in the laboratory[11]. There is no evidence of heterozygote advantage although this has often been proposed as a mechanism for maintaining melanic polymorphism. In the model, England and Wales are divided into squares with 22.5 km sides; mutation takes place at a rate of 10^{-6} per generation, and pollution in cities is assumed to have increased linearly for 55 years from 1830 and since then to have remained constant. The simulation, which incorporates experimental data on differential selection by predators, gene flow and spatially constant non-visual differences in fitness, was allowed to proceed for the 150 *B. betularia* generations from the beginning of the Industrial Revolution to the present day. It generates a distribution of melanics which is remarkably close to that found in modern populations, with an incomplete replacement of typicals even in the most polluted cities, and local patches of high melanic frequency in some unpolluted regions.

The best fit of Mani's predicted frequencies to those found in nature is obtained using estimates of non-visual

selection which differ slightly from those resulting from breeding experiments. Nevertheless, his results make it clear that the evolution of industrial melanism in *B. betularia* must depend in part on gene flow and on powerful non-visual selective forces whose nature is as yet unknown. There remain many other problems associated with this apparently straightforward example of natural selection. Why, for example, has the frequency of *carbonaria* decreased in northern England since the introduction of smoke control, but increased in the south[7]? Even for a melanic moth it seems that life is never as simple as made out in the textbooks. □

Acetylcholine receptor cloned east and west and . . .

FURTHER to the article by C.F. Stevens (*News and Views*, 28 October 1982), it should be added that the cloning and 90 per cent of the sequence of the α-subunit of the *Torpedo* acetylcholine receptor had already been reported by a group in Britain (K. Sumikawa, M. Houghton, J. Smith, L. Bell, B. Richards and E. Barnard *Nucleic Acids Res.* **10**, 5809; 1982). The group used a two-stage procedure to design a 19-base oligodeoxyribonucleotide as an efficient hybridization probe in the cloning. From cDNA sequencing, the amino acid sequence of a 24-residue pre-N-terminal signal peptide and about 90 per cent of the sequence of the α-subunit of the *Torpedo marmorata* receptor were determined. These sequences agree with the sequence for the α-subunit of *Torpedo californica* since published by Noda *et al.* in *Nature* (28 October) and reviewed by Stevens. The only differences are at positions 42 (Asn for Ser), 230 (Val for Gly) and 318 (Asn for Asp), all single-base changes which are probably due to the species difference.

The mRNA fraction used has also been shown to be that for the native receptor by an exploitation of the oocyte translation system in which it forms the functional ion channel of the acetylcholine receptor (E. Barnard, R. Miledi and K. Sumikawa, *Proc. R. Soc.* *B*215, 241; 1982). □

Corrigendum

In the News and Views article 'A growing role for reverse transcriptase' (Nature **299**, 204; 1982), reference was inadvertently omitted to a paper by S.Z. Hirschman, S.J. Vernace and F. Schaffner (*Lancet* **1**, 1099; 1971), containing the first description of a DNA polymerase activity in preparations of human hepatitis B virus.

Pool and ridge patterns in peat mires

from Peter D. Moore

FROM the air, a peculiar pattern of concentric crescents can often be seen in the pools and ridges of a peat mire. The pattern stems from the tendency of pools on sloping mires to lengthen at right angles to the slope so that they run along the surface contours rather than downhill. But why should the peat pools grow in this manner?

Many theories have been put forward and it is possible that the causes of pool growth may differ according to the climatic environment of the mire and whether the mire surface is supplied with ground water or is dependent entirely on rainfall. Patterned peatlands are most frequent in high latitudes[1], but they occur as far south as 55°N on the western fringes of Europe to about 46°N in Minnesota[2], and they have recently been described as far south as 36°N in Japan[3].

The boreal aapa mires occupy valleys and possess ridge and pool systems which traverse their entire width. It has been proposed that they owe their structure to ice pressure from the pool systems freezing in early winter[4] but, although the freezing process could intensify a pattern once it has begun to form, it is doubtful whether this is the initial cause[1]. Snow cover may lead to a limited development of ice in winter in many Finnish mires, yet patterns are still apparent, as they are in the patterned mires of Japan, which also receive considerable snowfall in winter.

Study of Japanese mires led Sakaguchi to put forward a different theory for the origin of the patterns[6]. He claims that the initial generation of a bank/hollow complex could result from lines of accumulation of plant detritus — 'thatch lines' — carried by flood water over the mire surface. Interestingly enough the idea was considered in relation for Finnish mires in 1920 by Auer[4], but was not favoured by him. Sakaguchi backs up his proposals with observations on detritus patterns on sloping lawns after floods, which do indeed produce patterns which compare closely to those observed on a larger scale on sloping peatlands. It is an explanation which needs to be re-examined, preferably by detailed stratigraphical studies, in Finland.

Such a model is not satisfactory for the rain-fed raised and blanket mire pool patterns, for here the surface movement of water is restricted to local drainage requirements, there being no ground water supply. In these, the linear arrangement of pools again follow the contours of slope, but in this case they are usually underlain by several metres of peat and the slope itself often results from the morphological features of the peat mass. The possibility that an entire body of peat may be unstable and moving gradually down slope was proposed by Troll[7] and developed by Pearsall[8], who considered the sloping edges of a globular peat mass on a slope as a series of concentric pressure ridges.

The idea was put to the test by Pearson[9] at Muckle Moss in Northumberland. As a result of detailed surveying of posts within the peat body from a fixed position beyond the mire, Pearson was able to show that some posts had moved by as much as 3–6 mm over a period of seven years. The mass movement of the peat was thus confirmed and the pool patterns at this site could be explained in terms of ruptures resulting from this stress. The explanation cannot be applied to all patterned peatlands, however, for the pool morphology does not always conform to that expected of peat ruptures. Pools are often shallow and frequently they develop on very gentle slopes.

Boatman, Grade and Hulme[11] suggest that pools initially form in hollows which are related to irregularities in the underlying, sub-peat surface. They are then maintained by biological processes in which the peat accumulation rate is less in the vicinity of a pool than at some distance from it. The actual extent of the pools will then be related to surface water availability, one function of which is climate[12]. Some recently published stratigraphical work in Caithness, Scotland by Smart[13], shows, however, that although pool systems may have a long history, they are not necessarily persistent in the sense that they retain specific positions and expand or contract from these[14]. So pool patterns may change in the course of time as the mire succession and peat accretion proceeds. Fortunately, that very accumulation of peat contains a detailed record of the history of the mire and further stratigraphical studies are the obvious way to find out how the peatland patterns emerge. □

AUTUMN BOOKS SUPPLEMENT

The pitfalls of bookmaking

The making of a multi-author book can be a long and frustrating business for all those involved — contributors, academic editor and publisher. Here Anthony Watkinson charts the sequence of events and describes what can go awry.

ALL RESEARCH scientists will have written papers in journals. Quite a few who have blamelessly reached middle age will be asked to write a chapter on their specialism in a multi-author volume, that is a book of newly commissioned contributions edited by a fellow scientist. All publishers meet people who will never contribute a chapter again because the experience has been too horrific. The edited book is where the publisher–author interface is raw and bleeding. What happens, and what can go wrong?

It is likely that our neophyte contributor (let us call him Campbell) will first be approached tentatively. A letter arrives from a well-known figure in his field, someone he met at a congress: Campbell is flattered, is likely to agree and then hears nothing more for months. Meanwhile the aspiring editor (Edwards, an energetic and ambitious man) has decided upon the field to be covered, has written a synopsis and picked a team of potential contributors, and is looking for a publisher. Contrary to general belief most books, like most journals, come to the publisher as ideas: few publishers are actually creative. Edwards's pitch (the form rarely varies) is as follows: the field is rapidly advancing/has reached a stage when a synthesis is desirable/has not been reviewed for 20 years (a chemist's argument this one); and although he would love to write a monograph, his commitments are too heavy/the literature is now too vast to be digested by an individual/the fractured nature of the field makes collaboration preferable.

. . . few publishers are actually creative.

There was a time when the handshake of the head of a publishing house, in the Athenaeum or over a cocktail on a roof in L.A., was a commitment enough. These days to the world outside "the publisher" is the relatively humble commissioning editor (here, Parsons). On receiving Edwards's proposal she has two tasks (the pronoun is carefully chosen on the basis of probability). First she takes advice, probably from both regular advisers and appropriate specialists. Advisers never *like* multi-authored books; they lack cohesion etc. Nevertheless, *on balance*, the synopsis appears to cover the ground, Edwards has a good reputation and, given a few judicious additions and subtractions, the proposal is worthwhile and should be accepted.

Parsons's second task is the filling-in of forms which vary from publisher to publisher, but which all aim to establish for the ruling accountants that the book will be profitable and will be profitable quickly enough. Parsons prepares a sales forecast (by imaginative extrapolation from sales of similar books) and on the same basis proposes a price. Some publishers arrive at the price first — the market price or what libraries are thought to find tolerable — and then subtract all the costs to check that the price is acceptable. Others begin by totting up the costs and then calculate the price that will produce the profit margin required by multiplying the "unit cost" (total cost divided by print number) by a certain factor, usually about six. Subtracting from the price the percentage average discount to booksellers and agents gives net income, out of which must come production costs (obtained from typesetters', printers' and binders' scales) and the royalty payment. What remains is the gross profit, which pays all the publisher's outgoings and overheads, leaving a net profit. A second calculation based on the forecasted rate of sales establishes that there will be an acceptable return on the investment within the first year or so.

In the case of Edwards's project the way ahead is now open. The book seems to be viable both academically and commercially. Parsons's final proposal is typical: the book is to be 100,000 words (300 printed pages) in length, comprised of ten chapters, and will sell at £25 with a print run of 1,500 copies. It is time to sign contracts, in which payment for Edwards and for Campbell and his fellow contributors may be a contentious point.

Almost all academic editors are these days offered royalties but contributors not necessarily. Sometimes there is a package: the editor gets a proportion and the contributors divide the rest. Other editors get the lot and make their own arrangements with their (probably medical) contributors. More common now is a royalty to the editor and a lump payment to the contributors, sometimes so much per page and sometimes a fixed sum per contribution, the publisher's argument being that the maintenance of tens of little royalty accounts is disproportionately expensive (overheads killing convenience like the problem of buying single nails). Whatever royalty is offered it is very likely to be a percentage of net income (list price less discount) not of list price: the computer is said to demand this. It used to be said — go for a royalty. However decreasing sales and lower real royalty rates nowadays mean that cash in hand is often preferable for the contributor.

Whatever the arrangement proposed, Campbell and his fellow contributors — maybe a little worried by now — should receive a contract within four months of first approach. If not, it could be that Edwards is hawking the book around less choosy publishers; alternatively, he has been told to shed a chapter or two and has not faced up to breaking the news to the contributors concerned.

Campbell's contract will be subsidiary to that between Edwards and the publisher. It may be a rather scrappy piece of paper but it must *clearly* state title and length of contribution, date by which the typescript should be delivered, who holds copyright and what reward is offered. The document is likely to bristle with misspellings, not surprisingly since in many firms the job of preparation is left to the filing clerk or an inadequately briefed contracts centre. Campbell should challenge any omission or ambiguity but it will need a mass revolt of all contributors to change the financial terms.

. . . it will need a mass revolt of all contributors to change the financial terms.

It is usually best for all concerned if copyright for a whole book is held by one body, whether publisher or learned society.

The date of delivery must be realistic: if it is less than nine months ahead no one will treat it seriously and if it is over a year the tempo is going to be very slow. Length of contribution is often vaguely expressed: does the publisher mean printed pages or A4 double-spaced typescript, and, if printed, which format ("print area" is the relevant term here, not page size)? If given in terms of number of words, does this include space needed for figures and references? In addition offprint provision is important to some — are none to be provided, or 10, 25 or even 50? These are gratis but what about the chance of buying more? Campbell should also check on free copies: he can expect one, with the possibility of buying more at a discount.

At this same time Campbell should expect to receive more than a contract. Certainly there should be notes to authors. Because publishers continue to reprint documents drawn up by long-dead production directors in the days of letterpress, demanding imperial units, World List citations and India ink illustrations on Bristol board, such anachronisms should be challenged. Academics whose drawing offices have gone in the cuts might delicately ask about in-house help or perhaps a little advance. Wizards of the SEM should check on technical points and on how many micrographs are expected.

Even more important is guidance about the aims of the book. When Campbell was first approached he is unlikely to have received a blueprint: now Edwards must set out in particular the content, the aims and the level of writing. Are references to be comprehensive (the computer search) or selective? Campbell may be asked for a synopsis to be approved and circulated: if he is, Edwards is doing his job.

In ten months' time the postman will in theory stagger up the path of Edwards's house with ten impeccably presented typescripts. In theory. Even a good editor can do little except badger the laggards with circulars and phone calls; and even a good contributor such as Campbell is forced to realize that writing chapters comes after writing papers, grant applications and lectures, and that there will be some delay: he asks for an extension of a couple of months, is given it and gets his chapter in within the year. In any one book most chapters trickle in over a period of a few months, giving the good editor time to send back for rewriting, rewrite himself, cut, argue about nomenclature, argue about facts, query the references and demand replacement illustrations — edit, in other words.

. . . even a good contributor is forced to realize that writing chapters comes after writing papers, grant applications and lectures.

If Parsons receives the complete typescript earlier than 18 months from contracts going out she will be lucky. There are always some dropouts and the chapter that is twice the length asked for, typed single-spaced, without margins and with illegible handwritten corrections, figures that no drawing office can handle and already screened half-tones. Campbell should be prepared for delays and demand the chance to update his chapter; he should also know that it is those projects which go on through several updatings over seven years or more that can kill friendships.

When Campbell knows that the typescript has been delivered in its entirety to the publisher (editors are quick to write to say this), what sort of schedule can he then expect? Book publishing like house buying is a succession of delays: before Parsons passes the typescript to the copyeditor, until the copyeditor gets to work, while queries are sent out all over the world and answers come back, after the marked-up manuscript goes to the typesetter, and so on through the proof stage (with revised proofs if needed) and on to printing and binding. Assuming reasonable efficiency, no holding back because of cash-flow problems, a prompt postal service and no industrial action in the printing industry, reckon a year from delivery of the complete typescript to publication.

Book publishing like house buying is a succession of delays.

During this period decisions have at various stages to be made within the publishing house. Before money is spent on outside suppliers (typesetters, printers etc.) Parsons has to go through the same sort of procedures as she did at contract stage but this time with a real typescript. Inevitably the extent (the length of the typescript) will be greater than bargained for however tough Edwards may have been. Typesetting and printing costs may not be much higher in real terms (production controllers in publishing houses have learnt many lessons in the past few years) but the projected print run will undoubtedly be shorter because of the poor sales record of similar titles over the same period. There will usually be two calculations to be made: first on estimates, the stage which corresponds to what the contracts call "acceptance"; and second on real costs (typesetter's and printer's bills) when the final price is set. Campbell and even Edwards will know little of the in-house agonizing. Quite frequently publishers fail to remember to tell the editor the selling price of the book.

At handover of the typescript, an unworldly academic editor will hope to be given a schedule for proofs. There won't be one. If all goes well the best hope is for proofs within six months but prior warning, let alone a schedule, is most unlikely. Production staff are surprised every year by the fact that proofs going out in the summer holiday and congress season don't get returned for months. Proofs always arrive at the most inconvenient time with an unrealistic three weeks turn-round demand, possibly reduced to a week by transatlantic postal delays. The usual system for an edited book is for contributors to return proofs to the editor, who collates them and returns a master copy to the publisher.

Suppose that the proofs are a mess. On the advice of the production department Parsons has opted for a cheap typesetter and for the money has got omissions aplenty, poor alignment of tables and an unhealthy crop of typographical errors. Campbell knows that he will be charged if the cost of making corrections is over 10 per cent of the original cost of the composition of his chapter. What can he do? He can certainly correct all mistakes that have been made by the typesetter — without fear of cost or complaint. Sometimes, however, such "mistakes" are the result of over-creative editing yet it is best to give in gracefully unless actual errors of substance have been introduced. When galley proofs were the rule authors used to rewrite in proof on the Proustian model (his galleys were famous) but the contributor of a chapter to a work of scholarship nowadays has no such chance. Each alteration means a series of actions by a highly paid operative; it can cost as much as £1 to add a comma.

Meanwhile Edwards has been contacted by the marketing department of the publisher. There is a publicity form to be filled in. The form will have asked optimistic questions about potential media coverage and the nature of the expected readership. The fact will be a badly typed regurgitation of his own summary of what the book is about, a list of places where review copies are to be sent (one hopes) and possibly requests for photocopies of the membership lists of relevant learned societies. He will not be asked about the jacket (there is unlikely to be one and the artistic design prepared by his wife may well have been lost) and there will certainly be no launching party. The best Edwards can do, poor soul, is cut down the claims (if he is a realist) and make sure that the names of all the contributors are spelled correctly.

For Campbell and his fellow contributors, the actual publication will come as an anti-climax. Edwards, being a keen editor, may have written to say that the book is "out" but his advance copy does not mean that the bookshops know about it, and it certainly does not mean that the contributors will have received their statutory free copies. Campbell, looking for reassurance, is unlikely to find it on the shelves either in the local bookshop, which received one copy on a standing order plan, or the library which bought the copy but has cataloguing delays. Publishers rarely advertise, except for a regular entry in a journal or two in which an individual title may receive much the same amount of ▶

Keeping it clean

R.C. Lewontin

Evolution and the Theory of Games. By John Maynard Smith. Pp.218. Hbk ISBN 0-521-24673-3; pbk ISBN 0-521-28884-3. (Cambridge University Press: 1982.) Hbk £18.50, $34.50; pbk £6.50, $11.95.

POPULATION genetics is the automobile mechanics of evolutionary theory. Population genetic theory is a deductive structure that asks the question: Given the mechanical details of inheritance, given mutation rates, recombination rates, migration rates, patterns of mating, the Darwinian fitnesses of various genotypes, and the relation between genotype and phenotype, how will the composition of a population or species change in time? The job of the theoretical population geneticist is to set up a mathematical machine into which the various parameters can be dumped, to turn the crank, and to produce the kinetics of evolution.

In practice this process has a number of serious difficulties. For even mildly complicated models involving several genes or non-random mating or non-constant fitness, the mathematical problems can be virtually intractable. Moreover, we do not usually know the genetic basis for traits of interest, nor are we able to measure the parameters in nature to any close accuracy.

As a consequence, evolutionists have continually searched for ways to avoid the dirty details of the kinetic equations of population genetics and to make predictions about evolution by some easier route. One form of approach has been to try to find laws of maximization or optimization, much as classical physics used Fermat's Principle of Least Action or the minimization of potential energy, in place of the kinetic equations themselves. To this class belong what R.A. Fisher called, with characteristic modesty, the Fundamental Theorem of Natural Selection, and Wright's principle of the maximization of mean fitness. Unfortunately, these maximization principles turn out not to apply generally, and the only way to know when they do is to solve the kinetic equations that we were trying to avoid in the first place.

Another attempt to make evolutionary predictions on the cheap was my introduction in 1961 of the apparatus of game theory into evolutionary biology. I had hoped that by drawing analogies — a population to the player, and the population's genetic structure and parameter values to a strategy — the entire apparatus of game theory could be used to make evolutionary predictions. But this attempt foundered on precisely the same rock as optimization theory: there is no guarantee that the actual kinetic process of gene frequency change will carry an evolving population to one of the so-called "solutions" in the game theoretic problem. That is, evolutionary equilibria are not necessarily the same as game-theoretic equilibria.

As luck would have it, I was visiting professor at Sussex University in 1971 when John Maynard Smith first began to reintroduce the metaphor of the game into evolutionary biology. At first, I was sceptical. The very words "Evolutionarily Stable Strategy" seemed to reek of the discredited attempts to avoid the messy realities of genetics. Only slowly did I come to understand that Maynard Smith was engaged in a totally different project, a project that is now lucidly explained in his new book *Evolution and the Theory of Games.* The name of the book unfortunately perpetuates a misunderstanding, for, with the exception of the metaphorical use of a few terms like "strategy" and "pay-off", Maynard Smith's theory makes no use whatever of game theoretical apparatus, but rather lies totally within the standard kinetic structure of population genetics. That is the secret of its success.

A central set of parameters for making predictions in population genetics is the set of reproductive fitnesses of the various genotypes in the population. In much of population genetic theory these fitnesses are assumed to be fixed constants characteristic of each genotype. Some progress has been made in building models that include simple dependence of fitness on population density, on the frequency of the genotype in the population, or on a fluctuating environment with known statistical properties. None of these models, however, deals with two important properties of organisms: first, any genotype may have a variety of phenotypes each with a different fitness; second, which phenotype is displayed and what its fitness is may depend upon the phenotype manifested by other individuals in the population.

This kind of doubly contingent fitness determination may make the average fitness manifested by each genotype rather difficult to compute, and so evolutionary prediction becomes very problematic. Animal behaviour in particular is full of such problems because an animal may sometimes act in one way and sometimes in another, while the fitness value of these actions will depend upon what other animals are doing. There is, then, a continuum of possible phenotypes, say from always being aggressive, through sometimes being aggressive, to always being passive, and every phenotype has a frequency-dependent fitness. And we have not even mentioned genotypes yet — not a very encouraging prospect for a theoretical population geneticist.

Maynard Smith's contribution has been to cut through this thicket by asking a somewhat more restricted question, the answer to which can be very powerful. He has developed a set of algorithms to find which of the patterns, when it is very common in the population, has a higher fitness than any other pattern that enters the population as a rare variant. The implication is that once this phenotype is established in the population, no other can displace it. Such a "King of the Mountain" phenotype is called an Evolutionarily Stable Strategy, or ESS. It turns out that such patterns exist for a wide variety of situations in animal conflict, in learned behaviour, in resource allocation and in a variety of other very complex frequency-dependent fitness problems. The real issue is whether these patterns live up to their name. Are they really evolutionarily stable?

It is at this point that the messy details of genetics reassert themselves. If the ESS pattern can be achieved by a homozygote or if reproduction is asexual, then the answer is yes. On the other hand, if the ESS pattern can only be produced by a heterozygote, then clearly it is not achievable in pure form in a sexually reproducing population. Moreover, some populations are genetically polymorphic. Can the ESS be stably created by a mixture of genotypes obeying the rules of segregation and recombination? The answer is "Sometimes yes and sometimes no". Thus, the phenotype that Maynard Smith calls ESS might better be called the "Frequently Roughly Evolutionarily Stable Strategy". A fair amount of argument in *Evolution and the Theory of Games* is devoted to convincing us that the genetic basis of behavioural phenotypes is likely to make a FRESS into an ESS. So, for example, single locus overdominance is said, probably correctly, to be rare, and it is asserted that if many genes influence a character, it is probable that any intermediate phenotype can be produced by an appropriate mixed homozygote. It must be pointed out, however, that epistatic gene interaction may be very important and that linked genes will produce a pseudo-overdominance that decays only slowly, if at all.

Other criticisms have been made of ESS theory, but Maynard Smith discounts them as being beside the point. So, predictions of ESS depend upon the set of alternative "strategies" that are evaluated. But precisely the same is true of all kinetic predictions in population genetics, which are based entirely on the alternative genotypes actually present in the population. Indeed, ESS theory has the advantage over vague optimization theories that it makes very explicit what the set of alternatives are that are being considered. ESS theory is not easy to check against natural observations because both the parameters and the predictions are usually in the form of relative frequencies that have immense standard errors, unless sample sizes are very large. But, again, that is a problem for all of population genetics, so ESS predictions are no more unfalsifiable than anything else in evolutionary genetics. The criticisms are to the point, however, when ESS theory is used uncritically, and it must be admitted that the very words "Evolutionarily Stable Strategy" have a kind of puffery about them that invites the same sort of overgeneralization as the not-so-Fundamental Theorem of Natural Selection. After all, evolution has been going on for three billion years, and if some strategy is evolutionarily stable, why surely that must mean that it is here to stay. The letters ESS now rival DNA as the most fashionable acronym in biology, and we may expect that many vulgarizers both outside and within evolutionary biology will simply not appreciate the contingency of the method.

There is a deeper sense in which ESS theory shares a flaw with all attempts to make general explanations for evolutionary events. At any moment we will see characters that are common to all members of a species, and we will be tempted to ask "Why is the species like that?". To give the answer "Because that is its optimal phenotype" is to give a totally uncheckable answer because we cannot ever know what set of alternatives was available to the species during the course of its evolution to its present state. To say that the codfish lays millions of eggs in order to maximize the number of survivors is to forget that it *might* have become ovoviviparous and so have provided maternal care. The same problem exists for ESS theory. We simply cannot say that a species is at an ESS because we do not know what set of alternatives was available. That is, such theories have predictive power but not explanatory power, *post hoc*.

On balance, ESS theory, because it is so firmly rooted in the kinetics of population genetics, must be judged as one of the more fruitful directions in theoretical evolution. Like other attempts at making generalized rules, such as the Fundamental Theorem of Natural Selection, or the principle of maximization of mean fitness, it works when the details of the genetic system are appropriate, but not always. Thus, we are still not free to ignore the material particularities that underlie phenomena. When all is said and done, "God is in the details". □

R.C. Lewontin is a Professor in the Museum of Comparative Zoology, Harvard University.

The man who was crunched by numbers

Richard L. Gregory

Charles Babbage: Pioneer of the Modern Computer. By Anthony Hyman. Pp.350. ISBN 0-19-858170-X. (Oxford University Press: 1982.) £12.50.

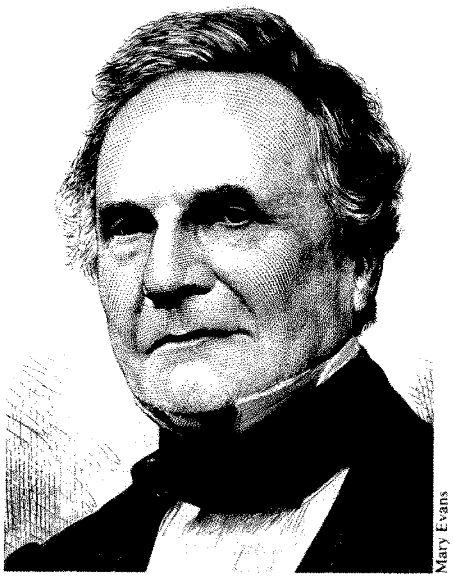
ANTHONY HYMAN'S biography of the inventor of programmable computers is no dry account of a premature technological innovation; and neither is it, as a previous biography, a shallow journalistic treatment of this truly remarkable man. Hyman has succeeded in bringing Babbage alive in the social context in which he played, as we may now appreciate, such a prominent part, and gives a clear account in just sufficient detail of Babbage's outstanding achievement, his Analytical Engine.

Charles Babbage (1791–1871) was born of a West Country banking family and became Lucasian Professor of Mathematics at the University of Cambridge (1823–1839). Elected to the Royal Society in 1816, he played a prominent if abrasive part in the scientific and technological life of his time; his influence extended to continental Europe, especially to Italy. As is well known, with advancing years he became a bitter and somewhat disappointed man; but this book shows the extraordinary range of his enthusiasms and his love of life. In retrospect he is far more to be envied than pitied, in spite of his famous defeats at the hands of Government, especially Peel's in the 1840s. Perhaps surprisingly, 20 years earlier Babbage was imaginatively supported by the Duke of Wellington when he was Prime Minister. As Hyman says (p.191):

> The underlying cause for this sad change was the developing Victorian academism. A wide gap was opening between the superior pure science of the Universities and inferior applied science, the bread and butter of the engineers Babbage's engines fell through this gap into a century's oblivion.

Those engines were only understood by a few people, among them Byron's daughter Ada, Lady Lovelace. Most difficult to grasp was the notion that in its progress towards solutions such a machine could be affected by its own findings. Wheeled calculators were known from Pascal's machine of 1642, so concepts of representing numbers and carrying out arithmetical and logical operations were fairly familiar — and indeed have been from the prehistoric abacus — though these vitally important concepts have received remarkably little comment or appreciation from philosophers; or perhaps even more surprisingly, from mathematicians or astronomers, or financial people who might have benefited greatly.

Like Helmholtz's Unconscious Inference and Freud's Unconscious Wishes, perhaps Babbage's computing engines were an unwelcome threat to human dignity; and to social and moral responsibility, for consciousness then as it still does, seemed necessary for blame and praise. Babbage's own attitude to blame and praise is convoluted. He rejected a knighthood, while also confessing to Ada that accolade and honours were particularly dear to him. He was justifiably upset that his Analytical Engine was excluded from the Great Exhibition of 1851; though he was no doubt delighted that his friend Charles Dickens based the HOW NOT TO DO IT OFFICE of *Little Dorrit* on Babbage's experience of Government's attitudes to those who have the wit to do new things.



Mary Evans

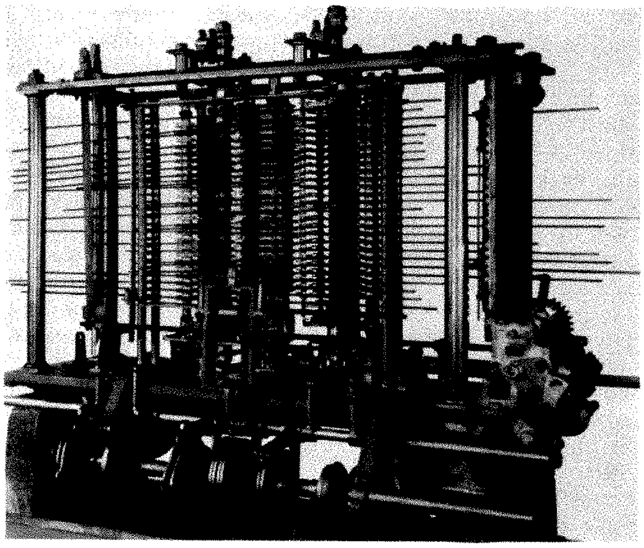
Charles Babbage, a man with a vision

Such contrasts run right through Babbage's life. He was so active in the society of the time that through Hyman's account one learns a great deal about this formative period of science and its relations with technology, as well as about Governments and how they dealt with novelty. Babbage was a man with a vision of the future industrial world as well as of computing; he was influential in the founding of several learned societies, as well as in the application of pure science in industry and commerce. He had an extremely active social life, too, being friendly with the great men of his time, and also appreciated the arts; on a splendid occasion when he was bored by a performance of Don Giovanni, he went behind the scenes and virtually invented modern theatre lighting. He invented the ophthalmoscope, and indeed everything he turned his hand to was affected by his touch. Babbage not only saw how the punch card system of Jacquard's loom could be used to control logical processes in a machine — and so how thought itself can be carried out by machinery — but, by almost superhuman effort, he developed precision engineering and mechanical drawing to a point where the general-purpose computer became very nearly if not quite a practical possibility. The full realization required the technology of electronics, but the basic concepts are there in beautifully fashioned cog wheels. (One is almost tempted to say cognitive wheels!). Babbage did as much as any man to create the machinery and the techniques — including engineering drawing — for precision mass production which has produced historically unimaginable wealth and knowledge.

All of this was achieved at the cost to himself not only of a large proportion of his personal fortune, but also in having to live with a painful gap between what he could see was needed and possible, and — for him — the stupidity and inertia of the society in which he lived. It is just this tension between his dream and our present reality that places Babbage as a man uniquely poised at the threshold of our age — leading surely to fully intelligent machines.

Anthony Hyman has succeeded in bringing the many themes of Babbage's experience and contributions together. His book is eclectic and thoughtful, as well as being both an inspiration and a warning to those of us who have faith in invention rather than received wisdom. ☐

Richard L. Gregory is Professor of Neuropsychology and Director of the Brain and Perception Laboratory at the University of Bristol.



Science Museum, London

Babbage's Analytical Engine, which stands in the Science Museum in London. The machine was never completed. Babbage had thought out all of the principles on which modern computers function, but not until a century later, and the rise of electronics, could his ideas be fully realized.

Entombed in print

P.B. Medawar

A Biographical Dictionary of Scientists, 3rd Edn. Edited by Trevor I. Williams. Pp.674. ISBN 0-7136-2228-8. (Adam & Charles Black: 1982.) £15, $30.

THIS admirable book first appeared about 12 years ago and the call for a second and now for a third edition is evidence enough of its fulfilling a real need, for although it is good value it is not cheap. The innovations of the present edition are the addition of supplementary biographies of some 40 scientists who have qualified for admission — as one day we all shall — by dying, for all is in the past tense. Another valuable innovation is the inclusion of an index which under a variety of subject headings lists the names of the scientists specially connected with each one. Thus under the subject heading "Evolution" we are referred to von Baer, Darwin C, Darwin E, Dobzhansky, Haeckel, Hooker, Huxley, Lamarck, Malthus, Maupertuis, Nägeli, Naudin, Pringsheim N, Spencer, Vallisneri and Wallace — which is fair enough.

It was a claim of the first edition that it addressed general readers as well as the student of science but it really does not go very far to appease the former: the entries are baldly factual.

In this edition the grounds for inclusion of a name in the main body of the text remain as mysterious as ever (the task of deciding must have been extremely difficult). The omission of such a prominent figure as Darcy Wentworth Thompson can I suppose be excused on the grounds that he did not found a school and is not now thought of as a man who was scientifically very influential, though he was greatly admired. Clearly priority has always gone to practising scientists rather than to men who are not primarily known as or indeed known to be scientists, however great their influence on the general public, on fellow scientists or on literature or the arts.

Thus there is no place for Goethe though he did some work which he probably thought of as scientific (the "vertebral theory of the skull", for example) and his commitment to *Naturphilosophie* which exercised a wide influence — undoubtedly a harmful one. But I was sorry not to see H.G. Wells who, although he held only a fairly minor teaching post in zoology, was the author of a widely consulted zoological text and had a profound influence on the young through his brilliantly imaginative short stories which were greatly superior in all respects to those of Jules Verne. Francis Bacon rightly rates inclusion, however, because of his profound influence in throwing off the hegemony of Aristotelian thinking and propounding a philosophy of science which is recognizably congruent with modern thought even if it was in some ways pretty wrong headed. He was not much of a scientist though, and one can understand why one of his biographers called him "a medieval philosopher haunted by a modern dream".

I did not spot any errors of fact but then, I was not looking for them, taking it quite for granted that a work of such great compass and of so many hands must surely contain a few mistakes, and being unwillingly to incur the deserved odium of picking them out and calling attention to them. In the outcome I rate this dictionary as a great success and a considerable feat of editorship and of publishing which will earn the continuing gratitude of all who have occasion to refer to it. □

Sir Peter Medawar is a member of the Scientific Staff of the Medical Research Council's Clinical Research Centre, Harrow, Middlesex.

Along the lines of Einstein's thought

Arthur I. Miller

'Subtle is the Lord . . .': The Science and the Life of Albert Einstein. By Abraham Pais. Pp.552. ISBN 0-19-853907-X. (Oxford University Press: 1982.) £15, $25.

"SUBTLE is the Lord, but he is not malicious", remarked Einstein to a colleague one day in 1921. When queried further on this statement he replied that "Nature hides her secret because of her essential loftiness, but not by means of ruse". Einstein's life-long passion was to pluck from the cosmos the laws of nature ("her secret") that exist independently of the scientist as knower. And what a passion it was.

During the period from 1905 to 1916 Einstein set the foundations of twentieth century physics with two lines of research. One line dealt with invariance principles and culminated in the special (1905) and general (1915) theories of relativity. Then there were the statistical researches that resulted in a theory of Brownian motion (1905) and a route to the verification of atomic structure, the light quantum hypothesis (1905), the first quantum theory of the solid state (1907), the wave-particle duality for light (1909), and the A and B coefficients (1916) that would lead to the laser. Finally, in 1925 came one more major piece of creative work, namely his argument, independent of Louis de Broglie, for the wave-particle duality of matter.

Thematically Abraham Pais's "scientific biography" of Einstein is set out along those two lines of Einstein's research because "better than anyone before or after him he knew how to invent invariance principles, and make use of statistical fluctuations". After 1916 these two strands merged into Einstein's quest for the unified field theory, an episode in the history of science that Pais explores systematically for the first time.

Among Pais's informative biographical sections are those describing how Einstein's feats during the intensely creative period of 1905–1916 were accomplished in the face of events that would have distracted all but the most determined: he worked dutifully eight hours per day at the Patent Office in Berne (1902–1909); he moved between academic positions at the University of Zurich (1909–1911), the German University in Prague (1911–1912), back to his alma mater that had virtually disowned him in 1900, the ETH, Zurich (1912–1914), and then to the summit of the scientific world, the University of Berlin and the Kaiser Wilhelm Institute (1914–1933); he married Miliva Maric in 1903, by whom he had two sons before they separated in 1914; and he had to deal with health problems and the deprivations of war time. Little wonder that in December 1915 after completing the theory of general relativity Einstein wrote to the venerable H.A. Lorentz that he was "satisfied but rather worn out [*kaputt*]".

The episodes written with the most verve are those describing Einstein's tortuous path to the general theory of relativity and then his work towards the unified field theory. The combination of new material and infectious prose in these chapters conveys to the reader some of the excitement of doing science.

As an example consider Pais's description of Einstein's work towards the general theory of relativity. In 1913, owing to Einstein's hitherto unsuccessful research towards generalizing special relativity, Pais describes Einstein as one "who stands alone . . . possessing only a vision" of which he is "supremely confident". Let us fill in a bit. Since 1907 Einstein had been struggling to generalize special relativity to include accelerating reference systems and gravity. A key realization, Pais writes, was that he had to "start all over again". Pais argues cogently that while in Prague Einstein had done just that by using a curved space-time that required a mathematics with which he was not conversant. "Grossmann, you must help me or else I'll go crazy", he said to Marcel Grossmann his former classmate at the ETH upon rejoining him there as a colleague in 1912. There followed a joint paper with Grossmann who wrote the mathematical portion, polemics with the "fearsome" Max Abraham, and exchanges with Gustav Mie and Gunnar Nordström. These men offered alternative gravitational theories

The Biology of the Coccidia

Edited by Peter L. Long

The Biology of the Coccidia is the updated version of *The Coccidia* edited by the late Dr Hammond and Dr Long. It includes a new chapter on chemotherapy and new details of life cycles of several species of Sarcocystis and Toxoplasma.

couched in variations of a four-dimensional flat space-time the "belief in which amounts, I feel, to something like a superstition", wrote Einstein to Erwin Freundlich in early 1914. Pais concludes that "Only Lorentz had given him some encouragement". In 1913 the doyen of German physics, Max Planck, listened to Einstein describe his work towards a general relativity theory and then told him that even if he succeeded "no one will believe you".

The onset of war does not affect Einstein's energy; the war years "rank among the most productive of his career". Amidst the tumult about him and his unsuccessful research on gravitation, in early 1915 Einstein turned to experiment in work on magnetism with Wander Johannes de Haas.

Then, in November 1915, the breakthrough occurred for the gravitation problem. He returned to the requirement of the general covariance of the field equations that he had "abandoned only with a heavy heart" in 1912. This time Einstein knew he was on the right track, because, Pais writes, "one week before the general theory of relativity was completed [25 November 1915] Einstein obtained" the correct result for the advance of Mercury's perihelion. Pais continues:

> This discovery was, I believe, by far the strongest emotional experience in Einstein's scientific life, perhaps in all his life. Nature had spoken to him. He had to be right.

There followed Einstein's prediction for the bending of light near the Sun and its verification by Arthur Stanley Eddington's Solar eclipse expedition in 1919; then was "Einstein canonized".

After 1920 Einstein left the mainstream of scientific research to pursue his vision of a generalization of relativity that unified electromagnetism and gravitation. The generalization would be based on the themes of continuity and classical causality, themes that were antithetical to the emerging atomic physics of Niels Bohr, Max Born and Werner Heisenberg. Pais asserts that Einstein had always considered a quantum theory as "provisional". He traces this strand in Einstein's thinking in great detail starting from the 1905 light quantum paper, complete with an illuminating analysis of the Bohr–Einstein dialogue of 1927–1930. Unfortunately, Pais rejects abruptly the important philosophical-physical analysis in the Einstein–Rosen–Podolsky paper of 1935 by quoting one of Bohr's *et cathedra* pronouncements of complementarity. Pais's reason, as he states straightaway in his book, is that "I would say that at his best [Einstein] was not" a philosopher.

Pais realizes that Einstein's decision to pursue a unified field theory poses a profound question that is ripe for historical analysis:

> Why does this man, who contributed so incomparably much to the creation of modern physics, remain so attached to the nineteenth century view of causality?

In outline his reply is: Einstein's infatuation with unification is evident from the beginning, as seen in his reaction to momentarily promising results from a 1901 paper where he compared intermolecular and gravitational forces — "a wonderful feeling to recognize the unifying features of a complex of phenomena", wrote Einstein to Grossmann in 1901. Although Einstein quickly abandoned the 1901 results, Pais considers that "this wonderful feeling sustained him through life". Then there was success with unification in special relativity (electricity and magnetism) and general relativity (geometry and gravity). These results, continues Pais, led him on a "quest for harmony" (geometrization of gravity and electromagnetism) based on the continuity and classical causality inherent in the differential equations of a classical field theory.

Here, and at other key points, it would have been appropriate for Pais to have developed Einstein's philosophical analysis of physical theory. Analyses of Einstein's scientific research that take seriously contemporaneous philosophical currents reveal that he was indeed a philosopher–scientist. While some lines of his eclectic philosophical view remained constant, others were transformed by his scientific research. Some investigation into this dimension of Einstein, and into other issues that are not readily apparent from the primary scientific literature, would have lent more depth to Pais's reply to a key question in the history of ideas. Pais's choice to exclude philosophical issues and his sparse use of recent historical scholarship is most costly to his analysis of special relativity theory — for example, on Einstein's invention of the theory and the theory's interpretation by Lorentz, Planck and Henri Poincaré.

Pais's forte is in the domain that he set out for himself; namely, to blend expository accounts of Einstein's complex physics with his scientific correspondence. This is no mean feat. A particularly valuable part of the book is where Pais goes on to bring research on gravitation and unification, as currently interpreted, up to date.

Abraham Pais is a distinguished physicist in his own right; his scientific biography of Einstein has clearly been a labour of love. The level of the scientific presentation is high, but so are the rewards, and the book fills in one part of the mosaic that is Einstein, his life, his times and his science. Together with such general biographical works as P. Frank's *Einstein: His Life and Times* and B. Hoffmann's *Albert Einstein: Creator and Rebel*, Pais's examination of Einstein's scientific oeuvre will be an important acquisition for both physicists and historians and philosophers of science. □

Myths of religion, myths of science

John Habgood

Abusing Science: The Case Against Creationism. By Philip Kitcher. Pp.213. ISBN 0-262-11085-7. (MIT Press: 1982.) $15, £10.50.

CREATIONISM, or "creation science", claims to provide a scientific alternative to orthodox evolutionary theory, in terms which bear a suspicious resemblance to a literal interpretation of the first chapters of Genesis. Its proponents are capable of stating their case with a display of scholarship which looks convincing to those who are not experts in biology, and their plea for tolerance, for a "balanced treatment" of creationism and evolution in school curricula, has made some disturbing headway in the United States. In alliance with the Moral Majority, creationists are now seen as a formidable threat by educationalists, scientists and non-fundamentalist theologians. As Philip Kitcher puts it "... although the Creationist campaign is advertised as an assault on evolutionary theory, it really constitutes an attack on the whole of science".

Kitcher's book is an impressive and absorbing counter-attack, which subjects all the main creationist arguments to detailed criticism. Those arguments are many and various, ranging from the accusation that evolutionary theory is unfalsifiable, to determined efforts to falsify it by appealing to palaeontology, thermodynamics, statistics, geology, uncertainties about transitional forms in the evolution of species — in fact any argument, however ancient or discredited, which seems to throw doubt on the evolutionist case. Kitcher relentlessly exposes the confusions, misunderstandings and misrepresentations on which the creationist platform is based, and provides, as he says, "a manual of intellectual self-defense" for those who find themselves under pressure. It is a splendid piece of demolition, but the effect is not merely negative. A valuable spin-off is his clear demonstration of the difference between science and pseudo-science, and this is why the book should be of interest even to those who stand outside the immediate controversies.

"THE MOST COMPLETE HISTORY OF THE ATOM TO BE PUBLISHED" *Energy Daily*

The Atomic Complex,

by Bertrand Goldschmidt is an accurate, complete and fascinating worldwide political history and personal memoir of nuclear energy — from the development of the bomb in World War II to today's nuclear energy complex and proliferation problems.

Goldschmidt, a leading French scientist turned international statesman, reviews half a century of political moves, countermoves, international intrigue and manipulation. ***The Atomic Complex*** is a pragmatic look at the nuclear world today, carefully examining the terror nulear weapons represent, but at the same time stressing the benefits of nuclear energy.

Why do intelligent people indulge in such silliness as creationism? The motive, despite tactical disclaimers to the contrary, is plainly a religious one, and it is a sad fact that for many Christians, particularly in the United States, Biblical literalism is still the rock on which faith is built. Kitcher attempts to meet this problem in a final chapter by a sympathetic treatment of religious faith, but the account is sketchy and this is the weakest part of the book.

The fact that creationists link their attacks on evolution with general denunciation of atheism, communism, nazism, behaviourism, racism and every other bugbear of liberal and illiberal thinking, is an extreme expression of a much more widely felt malaise. The fear that science can be dehumanizing is not confined to cranks. Sensitive scientists have always known that they are engaged in a human and fallible activity which entails adherence to some basic human values. But popularly, and in the mouths of some of its exponents, it does not come across like that. A hard, debunking kind of science which cuts human beings and their aspirations down to size too brutally, provokes its own reaction. The cure for creation science and its like, therefore, lies deeper than the arguments mustered here, important though they are. Scientists may claim that it is not their business to take care of human self-esteem, and that in any case the theory of evolution, by showing us where we have come from, does not reduce our worth. This is fair comment. But it is also true that the refusal to face questions about human worth in the name of scientific objectivity can easily give the impression that such questions do not matter.

It is not enough, therefore, to expose religious obfuscation. The appeal of movements such as creationism will not be undermined until ordinary people feel in their bones that religious and scientific experience can be properly integrated. *Abusing Science* is a useful first step in clearing away some of the rubbish.

I have, however, one small niggle about the book. Kitcher begins by referring to the famous encounter between Bishop Wilberforce and T.H. Huxley at the British Association in 1860. This has become part of the mythology of science, but it is a gross libel on Wilberforce to classify him as a nineteenth-century equivalent of today's creationists. In his day there were good scientific arguments to be levelled against Darwinism, and the fact that he used ridicule unwisely does not affect the genuineness of the issues at stake. The point about creationism is that the arguments are now known to be worthless, so that twentieth-century religious polemic in pseudo-scientific dress belongs to quite a different moral dimension. Scientific myths, like religious ones, sometimes need to be allowed to die. □

Curing nonsense

Stuart Sutherland

Pluto's Republic. By Peter Medawar. Pp.351. ISBN 0-19-217726-5. (Oxford University Press: 1982.) £12.50, $25.

THE intelligensia's attitude to science is becoming increasingly ambivalent. While resenting their dependence on some of its products and fearing the dangers of others, they rejoice at the least hint that there may be something wrong with a well-established scientific theory. This propensity is encouraged by the wilful ignorance of newspaper correspondents, as witness the recent nonsensical attempt to treat cladistics and punctuation as disproofs of Darwinian theory.

Yet despite this aversion to science, nothing is more calculated to lend credence to shoddy thinking than the claim, however far fetched, that it is scientific. Psychoanalysts repeatedly make this assertion about their subject and many universities to their shame have attempted to conceal the vacuity of their social studies courses by calling them "social sciences". In a recent tome on English literature, Mr Leon Edel even claims to be practising "scientific" literary criticism. It is a pity that those in arts subjects have so little faith in what they are doing that they feel obliged to dignify it with the name of science. The confusion of the intelligensia is further illustrated by the fact that they increasingly take refuge in the gibberish of such authors as Lacan, Laing and Levi-Strauss and in such creeds as ethnomethodology, where nothing is true but thinking makes it so.

Unfortunately, few scientists have the time or the patience to expose the nonsense produced by what Sir Peter Medawar calls "the intellectual underworld", and we should be grateful to him for appointing himself a defender of reason and for untoppling some of its assailants. It is true that most of the denizens of *Pluto's Republic* are more fools than knaves, but they are none the less harmful for that.

The book incorporates two of Sir Peter's previous collections of essays, and also includes a dozen or so essays not previously published in book form. It is pleasant to reread such classic exercises in debunking as his reviews of Teilhard de Chardin's *The Phenomenon of Man* and Arthur Koestler's *The Act of Creation*, even though both books are now largely forgotten. Nothing is more difficult than exposing nonsense since one cannot refute an argument where none exists. For the most part Sir Peter exposes the authors he is attacking by direct quotation, though he cannot resist adding his own ironical asides. For example, having quoted from Teilhard "Consciousness was now leaping up and boiling in a space of super-sensory relationships and representations", he adds "The analogy . . . is with the vaporisation of water when it is brought to boiling point, and the image of hot vapour remains when all else is forgotten". He is also good at showing how a thesis leads to untenable conclusions. He points out, for instance, that since according to Koestler laughter is produced by the "bisociation" of two incompatible "matrices" of thought, the disproof of a scientific theory should produce gales of laughter. As Sir Peter remarks, "We are not amused". Irony fails him in the face of the fatuity of a passage from one of R.D. Laing's associates, David Cooper: "Curing usually implies the chemical treatment of raw materials so that they may taste better, be more useful, or last longer. Curing is essentially a medical perversion". Sir Peter's recurrent assaults on psychoanalysis are, however, more amusing than original.

His onslaughts are interspersed with the Johnsonian thump of common sense. He remarks, for example, of dreams that they may merely be noise conveying no information whatsoever, and of Levi-Strauss's insistence on the scientific validity of the Siberian myth that the touch of a woodpecker's beak will cure tooth ache: "Would not someone actually suffering from tooth ache incline towards a more pragmatic style of belief?". His common sense is also illustrated in a recent essay demonstrating that economists can never make accurate predictions: among other obstacles is the fact that the predictions may themselves influence the state of the economy. And he presents a sensible defence of genetic counselling: "Scientific evidence bears on decisions which are not of course themselves scientific".

He also resembles Dr Johnson in his capacity to write with an air of authority even — as occasionally happens — on topics he seems to know little about. For example, he asserts that intelligence cannot be measured by a single number and that there cannot be such a thing as a "culture free" test of intelligence, but he makes no reference to the extensive research on both topics.

About a third of his new book is devoted to the philosophy of science. Although these essays are a little repetitious, Sir Peter provides a clearly stated summary of Karl Popper's position, to which he has added with considerable historical erudition an account of the work of some of those, such as Whewell, who anticipated Popper many years ago. One cannot help wishing that Sir Peter had taken up his sword to destroy some of Popper's apostates such as Feyerabend, whose confusions are as much in need of exposing as those of Teilhard or Koestler.

Although not everything Sir Peter has to say is original, it is always well said. It is a truism that among academics scientists write better than those in arts subjects, but he writes exceptionally well even for a scientist. He is never short of an apt quotation, a nicely chosen simile ("They accepted the contemporary and far from adequate form of Darwinism in much the same way that nicely brought up people accept their religion, that is, in a manner that contrives to be both tenacious and perfunctory"), or a witticism ("Haldane was totally lacking in worldly sense, a sulky innocent, a whole-hearted believer in *Them* — the agents of that hidden conspiracy against ordinary decent people, the authorities who withheld the grants he had never asked for and who broke the promises they had never made").

Bern Schwartz

Sir Peter Medawar — the Johnsonian thump of common sense.

Sir Peter has invented a literary genre of his own, which might be called *belles-sciences*, though he is perhaps at his best when he is exposing nonsense, of which there is still an abundance. If he thought *The Act of Creation* boring, let him try reading Lacan. □

Stuart Sutherland is Director of the Centre for Research on Perception and Cognition at the University of Sussex.

Nuts about PK

Martin Gardner

Psychokinesis: A Study of Paranormal Forces Through the Ages. By John L. Randall. Pp.256. ISBN 0-285-62540-3. (Souvenir Press: 1982.) £8.95.

MANY worthless books by writers who call themselves parapsychologists have been published in recent years, but *Psychokinesis* by John Randall, a biology teacher at Coventry School, tops them all. It is not just that he rakes over stale ground but that his book is hopelessly out of date.

Consider, for example, his enthusiastic endorsement of the psychokinetic (PK) powers of Uri Geller, the Israeli magician turned flim-flam artist. Randall makes much of John Taylor's high praise of Geller, and of the spoon-bending children featured in Taylor's book *Superminds* (Macmillan, 1973). He never informs his readers that in 1978 Taylor executed a 180-degree turn and denounced all psychic metal bending as fraud. Taylor even wrote a book about his disenchantment: *Science and the Supernatural,* published by Dutton in 1980.

Consider the pages in which Randall rhapsodizes over Geller's alleged alteration of the chemical structure of a piece of nitinol wire, giving it a new "memory" which experts could not remove. That is totally false. Eldon Byrd was in error when he made this sensational claim, reporting on his nitinol tests with Geller in Charles Panati's now discredited anthology, *The Geller Papers* (Houghton Mifflin, 1976). Experts at the Lawrence Livermore Laboratory, in California, removed the wire's memory easily. This was carefully detailed in my paper, "Geller, Gulls and Nitinol" (1977) (reprinted in *Science: Good, Bad and Bogus*), but either Randall never read it or, what is worse, read it but did not want to mention it.

Consider too the section in which Randall extolls the "thoughtography" of Ted Serios, a Chicago bellhop, who for a short time was apparently able to project onto Polaroid film his memory of photographs he had seen earlier in magazines. No one, says Randall, ever found evidence of trickery. Nonsense. In 1967 Charles Reynolds and David Eisendrath published in *Popular Photography* a complete exposé of how Serios performed his whimsical trick. Ted has been unable to replicate it since, although magician James Randi demonstrates it regularly and with more skill. Did Randall know of this exposé? If not, his research was amateurish. If he did, his failure to discuss it is reprehensible.

The sad fact is that Randall buys almost everything on the psi scene no matter how flimsy the evidence. He believes the PK is behind the spirit rappings and the table liftings produced by great mediums of the past. Many pages describe the levitations of human bodies from early Christian saints to meditating yogis; Randall suspects that PK helped Nijinsky make his high leaps on the ballet stage! He is persuaded that PK can hurl heavy objects across a room, move the hands of a clock and cause light objects, such as matches and pill boxes, to "walk" across a table.

A postscript summarizes the 1981 "minilab" phenomena recently disclosed by W.E. Cox, a former associate of J.B. Rhine and a confirmed Gellerite. Leather rings link and unlink. A pencil rises in the air and writes on a notepad. Randall assures us that Cox captured all these wonders on film, but he doesn't reveal that the films are peppered with time breaks, and that Cox's efforts to prevent fraud were so minimal that when he presented his stop-action films at a parapsychology conclave last year in Syracuse, New York, they were greeted with derision.

Randall even thinks PK is behind an old parlour trick in which four people use extended little fingers to hoist a heavy person from a chair. Samuel Pepys describes it in his *Diary* as a pastime of French schoolgirls. Geller does this stunt often in his stage act, using a fat man from the audience and three volunteers to assist him in the lifting. (By including himself among the lifters Geller can make sure the lift fails on the first attempt when PK forces are not invoked.) Hilarious photographs of Colin Wilson being "levitated" in this manner are in his preposterous book, *The Geller Phenomenon* (Aldus Books, 1976). "As far as I know", writes Randall, "no physicist has ever given a 'normal' explanation of this phenomenon".

What is there to explain? The first lift is uncoordinated. When it is repeated, after a preliminary ritual of some sort, the four lifts are synchronized, the weight is thereby evenly distributed four ways, everybody tries harder and up goes the fat man.

Randall believes everything. Well, not quite. He is surprisingly sceptical about what parapsychologists call "animal psi". When Helmut Schmidt's cockroaches seemed to use their PK to bias an electronic randomizer, Randall suspects it was not cockroach PK that did it, but PK from Schmidt or one of his assistants. Randall himself has pubished papers on how an experimenter's PK can influence animal life; in one case it modified the paths taken by crawling wood lice, in another test, the direction in which gerbils jumped. He was unable to replicate the positive results of a 1952 experiment by Nigel Richmond in which Richmond's PK influenced the paths of swimming paramecia.

To explain PK Randall dredges up an old theory, popular with Spiritualists a hundred years ago, that psychics somehow have the power to shift matter in and out of hyperspace. This was the opinion of a German physicist Johann Zöllner, to whom Randall devotes an entire chapter. Zöllner used the theory to account for the sensational results of his experiments with the famous American slate-writing medium, Henry Slade. His book about Slade, *Transcendental Physics* (English translation, 1880), is almost as funny as Jule Eisenbud's *The World of Ted Serios* (Morrow, 1967). Randall thinks I was unfair to Zöllner when I once called him "a remarkably stupid fellow". On the contrary, Randall is convinced that Zöllner was an astute investigator of Slade's genuine powers.

Randall's bibliography of 193 references is notable only for its omissions. Where, for example, is Edward Girden's classic paper, "A Review of Psychokinesis" (*Psychological Bulletin* **59**, 353–388; 1962)? In view of Randall's claim that magicians have no idea how Geller does his tiresome tricks, why does he neglect to list two books on sale in magic shops, *Confessions of a Psychic* (Karl Fulves, 1975) and *Further Confessions of a Psychic* (Karl Fulves, 1980), both by Uriah Fuller, which give Geller's techniques in full detail?

Uninformed readers may find Randall's book persuasive, but most professional parapsychologists will be as embarrassed by it as they are by the scribblings of such irresponsible journalists of the occult as Colin Wilson, Lyall Watson and D. Scott Rogo. *Psychokinesis* is only the latest, but surely not the last, of a seemingly endless line of lurid books about the paranormal, hacked out by gullible believers who are incapable of distinguishing competent investigations from shabby research and anecdotal poppycock. ☐

Neotony: is the child father to the man?

P.E. Bryant

Growing Young. By Ashley Montagu. Pp.306. ISBN 0-07-042841-7. (McGraw-Hill: 1981.) $12.95.

It is easy to detect a certain general ambivalence about the significance of childhood. On the one hand children seem to have some admirable and quite distinctive talents: they learn, for example, some very complicated things such as language (and sometimes two or more languages) with astonishing ease and they impress us with their quickness and their inventiveness. But on the other hand child psychologists keep on telling us that children lack many essential and therefore desirable qualities, and indeed these professionals devote much energy and ingenuity to the goal of hurrying on children's "development" and making them more like adults as quickly as possible.

Several people seem to manage to take both points of view at the same time even though the two obviously contradict one another. Ashley Montagu is not one of these people. His book is devoted unambiguously and enthusiastically to the proposition that childish qualities are not only desirable: they are, he thinks, precisely what distinguishes us from other species.

There are two parts to his thesis, the first anatomical and the second behavioural. The first part is the more familiar of the two and it also has more empirical support than the second. Neotony, a theory originally put forward by Bolk and lately extended in a well-known book by Stephen Gould (*Ontogeny and Phylogeny*; Harvard University Press, 1977), is Ashley Montagu's starting point. He takes up the argument that adult human beings preserve more of the physical features which characterize their childhood than do the adults of other species. Moreover, he argues, childhood takes up a larger proportion of the life span of humans than it does of other species. This, as far as the author is concerned, is not just a quantitative difference. He dwells on the evidence that human babies are born at an early gestational stage, and suggests that this is a significant factor in the quality of human social relationships. His argument is that much of family life is influenced by the need to protect and nurture helpless human infants.

Ashley Montagu — enthusiasm for neotony.

Having made this case persuasively and clearly the author then tries as well to make a direct connection with behaviour, and here he is notably less successful. His theory is that neotony is not just a matter of anatomy; human behaviour too, he claims, is strikingly "neotonous". The author attributes man's evolutionary success to the retention of traits which are characteristic of human childhood. These so-called "neotonous traits" include curiosity, creativity and sensitivity. Ashley Montagu's idea is that these are childish things which adults, and particularly those who are successful or at least admirable, retain through their lives.

There are several things wrong with this second part of the book. One is simply that the author rarely produces anything like convincing evidence for his thesis. There never has been any evidence at all that children are more creative than adults, for the very good reason that we have never had any good measures of creativity. The author's discussion of what pathetically unconvincing measures there are is strikingly uncritical and not even up to date. But his case is even less compelling when he talks about sensitivity, or flexibility or optimism (all of them put forward as neotonous traits), for here he can produce no evidence at all. Too often he is reduced either to stating his own unsupported impressions or to quoting the equally unsupported opinions of other theorists.

Another problem is that Ashley Montagu's (always attractive) enthusiasm for his neotonous case is so strong that he seems unable to notice that his thesis is, as far as several other people's theories are concerned, an antithesis. He gaily quotes Piaget, and yet apparently fails to notice that Piaget spent his whole working life trying to prove the startling intellectual inadequacies of childhood. The contrast between Montagu's optimism and Piaget's pessimism about childish behaviour is stark indeed: I cannot see how they could both be right. But there is no reason why Montagu should be worried by this, since there is now plenty of evidence that Piaget's gloomy stance was, to say the least, exaggerated.

This leads us to another difficulty about the book. Not only does the author skirt round possible arguments against his thesis; he also ignores a great deal of evidence which could be used to support it. The last ten years or so have seen a series of extraordinarily striking experiments which apparently demonstrate that even very young children have intellectual capacities which had been previously thought to come much later on in life. Since this research seems to show how sophisticated and effective even very young children are, it really is right up Ashley Montagu's street. Yet he all but ignores it. So we are left with a book which may indeed be right, but right often for reasons which the author himself leaves out. ☐

In between ethology and neurophysiology

R.M. Seyfarth

The Human Primate. By Richard Passingham. Pp.390. Hbk ISBN 0-7167-1356-X; pbk ISBN 0-7167-1357-8. (W.H. Freeman: 1982.) Hbk $19.95, £14.95; pbk $10.95, £7.50.

A GOOD science book, one is told, does not just organize and summarize results: it presents a novel synthesis of previous work, offers new hypotheses and points the way to new areas of investigation. This is a difficult task in any field, but it promises to be particularly frustrating when the chosen topics are evolution, the brain, intelligence, and language in human and non-human primates. Not only is this research scientifically complex, but it also has uncomfortable Cartesian overtones, since in the long run it aims to establish a boundary between human beings and other animals. Moreover, there's Catch-22. The more we find human features in the brain or in the communication of non-human primates, the more these animals become ideal models for research on human pathologies. At the same time, increasing evidence of similarities between human beings, apes and monkeys raises serious ethical and scientific questions about the conduct of such laboratory research. The ethical questions are being debated — for example by Marian Dawkins in *Animal Suffering: The Science of Animal Welfare* (Chapman & Hall, 1980). Now Richard Passingham raises some of the scientific issues that are equally worthy of consideration.

How should we characterize a brain that is so much like our own and yet clearly different? Where do the intellectual talents of monkeys and apes end and our own unique abilities begin? Is it wise, given the extraordinary anatomical similarities between ourselves and other primates, to assume a quantal difference between our language and their communication? In addressing these issues Passingham sets himself a considerable task, and it is a testament to his efforts that he partially succeeds.

In my view, the least interesting chapters are those on non-human primate relatives, technology, and culture, in which the author simply reviews areas that are traditionally covered in most biological anthropology textbooks. There are other chapters, however, where the material itself is not new but where the author juxtaposes studies that have not previously been treated together. In Chapter 5 Passingham nicely connects laboratory studies of animal intelligence (usually found in psychology textbooks) with field research on the same species (usually found elsewhere). Similarly, in Chapter 6 he tries (with less success) to link the laboratory "ape language" projects with research on the communication of primates in their natural habitats. Although such field and laboratory studies seem obviously related intellectually, *The Human Primate* is, surprisingly, one of the first books to treat them together.

This said, novel syntheses can be frustrating because they often reveal more about biases and failures than about insights and successes. Take intelligence: here Passingham reviews the correlation between performance on a variety of psychological tests and at least one index of brain development. To no one's surprise, monkeys and apes score better than other mammals. Insufficient emphasis, however, is placed on the fact that as yet we have no test that reliably distinguishes between the skills of apes and of Old World monkeys. Somehow we *know* that chimps are smarter than macaques, but thus far comparative psychologists have been unable to describe what this actually means. Even when species differences in test performance are found, no successful effort has been made to determine the relation between such scores and the animals' natural social behaviour. For instance while Clutton-Brock and Harvey have shown that primate species with larger brains have larger home ranges, to those interested in how intelligence works and has evolved this remains nothing more than a tantalizing correlation.

Similarly, in other sections Passingham synthesizes two studies on one page, only to adopt a page later the same narrow perspective that has kept them apart for so long. In comparing the "ape language" studies with research on the natural signals of chimps, he correctly notes that evolution is unlikely to have supplied an animal with communicative skills for which it has no need. Thus we should expect, if only as a working hypothesis, to find that free-ranging chimps or other primates are capable of using sounds or other signs to represent objects in the world around them. Passingham concludes too readily that there is no such evidence. The fact is: no one has really looked. For while the ape language projects have begun on the assumption that their subjects are capable of at least rudimentary semantics, observers of the same or related species in the wild have generally not even considered this as a possibility. Given such biases, it is not surprising that few parallels have been found between primates' abilities in the laboratory and their natural communication in the wild. But it would be premature to conclude that no such continuities exist when, until recently, they haven't even been considered.

The Human Primate makes its most important contribution, and has the most to say about the future conduct of research on non-human primates, where it addresses studies of brain mechanisms,

The latest research findings are presented in these new volumes —

Membrane Recycling
Ciba Foundation Symposium 92
The fundamental unit of all human and animal tissues — the cell — is bound by a fluid surface membrane. This wrapping is the means by which the cell interacts with its environment. Changes in the membranes and the effects of their mobility form the subject of this major international symposium.
Hardback/320 pages/Price £25.
0 272 79656 5

Mobility and Function in Proteins and Nucleic Acids
Ciba Foundation Symposium 93
Technological advances over the past two years have caused rapid progress in research on mobility in proteins and nucleic acids. This symposium describes recent work on mobility and its functions in enzymes, proteins, muscle, collagen and elastin, and nucleic acids.
Hardback/320 pages/Price £25.
0 272 79657 3

Malaria and the Red Cell
Ciba Foundation Symposium 94
This volume covers in detail the way in which the malaria parasite enters the red blood cell — and there is much new research in this area. The haematological, biochemical, immunological and pathological consequences of red cell invasion are considered, as are the ways in which these may be modified by different red cell types.
Hardback/320 pages/Price £25.
0 272 79658 1

Brush Border Membranes
Ciba Foundation Symposium 95
Brush border membranes are known to occur in the gut, kidney and placenta. In this volume, the topology, biosynthesis and assembly of enzymes, attachments between membrane and cytoskeleton. Cell contractility, and transport through the membranes, are discussed in the light of recent research.
Hardback/320 pages/Price £25.

language and communication. Consider, for example, the search for neural lateralization in non-human primates, or for non-human primate analogues of Broca's and Wernicke's areas in the human brain. Here Passingham's lucid review makes one aware that most research thus far has been a curious combination of highly sophisticated neurophysiology and behavioural assays that are crude and primitive by comparison. When the subjects are human beings, every effort is made to see that they live as normal lives as possible, and that they are tested with meaningful stimuli like words, pictures and other conspecifics. In contrast monkey subjects are often kept in isolation cages and tested with tones, hisses and human speech. Under these conditions is it any wonder that parallels in brain function are often hard to find? Passingham's review offers a challenge for future research, because it shows clearly that good neurophysiology requires equally good ethology. In order to understand the monkey's brain we must also understand — and respect — the social environment in which it has evolved. ☐

Robert Seyfarth is in the Anthropology Department at the University of California, Los Angeles.

Race is everything

W.F. Bynum

The Idea of Race in Science: Great Britain 1800–1960. By Nancy Stepan. Pp.230. UK ISBN 0-333-28856-4; US ISBN 0-208-01972-3. (Macmillan Press, London/ Archon (Shoe String Press), Hamden, Connecticut: 1982.) £20, $27.50.

IN LIBERAL circles nowadays, "race", if not exactly a dirty word, is at least one which can be vaguely embarrassing. Modern anthropology stresses social forms rather than biological natures as central to the differences between "us" and "them". This was not always the case. As the Scottish anatomist Robert Knox wrote in 1850, "Race is everything: literature, science, art — in a word, civilization, depends on it". To be sure, Knox was a little bit suspect even in his own time, since his religious views were heterodox and he had been the prime recipient of the merchandise purveyed by Burke and Hare. But Knox's racial theories were part of the nineteenth-century fascination with the subject, and not simply as it related to the variations between Hottentots and Englishmen. Anthropology could be studied closer to home: in the differences between the Saxon, who built his detached home in splendid, self-reliant isolation, and the Celt, who swarmed in the slums of the teeming Victorian cities. Norman yokes and Aryan races were part of the substance of nineteenth-century science.

The title of Nancy Stepan's new book is significant: *Race in Science.* Concentrating primarily on Britain, she traces the rise of the scientific idea of race in the eighteenth century, through its burgeoning in the next century, to its decline in our own. The peripheries are rather fuzzy, for there was a preoccupation with the nature of human differences long before the Enlightenment, and the modern legacy of old-fashioned racial studies (what Stepan calls the "new science of human diversity") is not without its historical reverberations. Not ten years ago Britain's oldest university press published a massive book by a Fellow of its oldest scientific society entitled simply *Race.* Nevertheless, Stepan insists, the

> tradition of scientific racism which had lasted from the early nineteenth century until the end of the Second World War if not later, has at long last been laid almost to rest.

The phrase "scientific racism" raises issues which, as we shall see, Stepan is conscious of but does not resolve. But what she does, soberly and cogently, is to describe the idea of race in Britain during the past two centuries. Her book is based on an intelligent reading of the relevant primary and secondary literature, and the result is a thoughtful, well-written synthesis. Three principal themes successively dominated debates on race during the period Stepan covers: the original unity or diversity of mankind; man's evolutionary origins; and the relative eugenic worth of the various human races.

Traditional theological and scientific orthodoxy asserted that all human beings are descended from a single pair, created by God and placed in the Garden of Eden. In the nineteenth century, this monogenist view was most authoritatively developed by the Bristol physician and ethnologist James Cowles Prichard (1786–1848). In a series of erudite books, culminating in the five-volume, third edition of his *Researches into the Physical History of Mankind* (1836–1847), Prichard marshalled the anatomical, physiological and linguistic evidence favouring the original unity of man. His Christian vision inspired many of the founders of the Ethnological Society of London (1843), but by the time of Prichard's death a more secular, continental-inspired polygenism (as represented by Knox) was rapidly gaining ascendency in British circles. This mid-century polygenism was rooted in the notion of the biological *type* and stressed the permanency of inheritance at the expense of the more fluid environmentalism of earlier naturalists.

After 1859, of course, Darwinian evolution and the contemporary discovery of man's antiquity gave a broader framework for theories of the origin of human beings and human races. Curiously enough, as Stepan correctly insists (echoing a point persuasively argued by the historian of anthropology George W. Stocking, Jr), late nineteenth-century debates were often couched in roughly the same terms as pre-Darwinian ones. Polygenism persisted long after evolutionary biology might have been expected to have made its traditional formulation irrelevant. Part of the intellectual reason is that typological thinking can be neater and more satisfying than the population or statistical thinking inherent in Darwinian definitions of species and in the Darwinian vision of nature.

Statistics, however, was also central to eugenics, named and inspired by Darwin's cousin Francis Galton. In Britain, eugenicists were generally more concerned with social class than with race, although Stepan deftly picks her way through the eugenics movement, focusing on the all-too-easy transition from class to race. Both eugenics and racial biology in Britain were profoundly affected by the revulsion to Nazi ideas and practices, and the establishment of the neo-Darwinian synthesis by Ronald Fisher, J.B.S. Haldane and Theodosius Dobzhansky gave new sophistication to population genetics at the expense of the typological approach. Since the Second World War, the main arena for these debates has been the psychological laboratory rather than the anthropological field station, as the nature–nurture polarity has revolved primarily around intelligence. In the United States, which at least until the recent past has had a more turbulent racial history than Britain, Arthur Jensen's researches have racial overtones; in Britain, Cyril Burt's data were aimed at showing class differences in intelligence.

Stepan discusses all these issues and more in a book which has many virtues. What she does not do, however, is explore analytically the implications of one of her explicit working assumptions:

> that though the connection between racism and science is inescapable, the story of scientific racism is not merely a story of "pseudoscience". Bad science, perhaps, but not pseudoscience [p.xvi].

Her work hints at, but never comes to grips with, the relation between "science" and "prejudice", and between "good" science and "bad" science; with the nature of scientific knowledge; or with those wider issues of class, sex and empire, fact and value, which are central to that telling phrase, *scientific racism*. To write such a book would be vastly ambitious, but it should be possible even within Stepan's own liberal historiographical framework. In the meantime, her present book deserves to be read and pondered by anyone interested in the human sciences or their history. ☐

W.F. Bynum is at the Wellcome Institute for the History of Medicine, London.

Theoretical archaeology in Melos

Peter Warren

An Island Polity: The Archaeology of Exploitation in Melos. Edited by Colin Renfrew and Malcolm Wagstaff. Pp.375. ISBN 0-521-23785-8. (Cambridge University Press: 1982.) £35, $65.

From 1974 to 1977 the Greek island of Melos was the subject of a multidisciplinary environmental survey, the fieldwork being closely integrated with excavations at the great Bronze Age site of Phylakopi. An account of these excavations, directed for the British School at Athens by Professor Colin Renfrew, will be published separately. The present volume has as its basis the publication of the survey. There are 15 contributors, J. Cherry, C. Renfrew, B. Sparkes and M. Wagstaff writing major parts. Most of the team involved are or were at the University of Southampton and the volume must certainly rank as a major research achievement of that institution.

The project was concerned with the economic, social and political history of Melos, from the Neolithic period to the present, in relation to the island's whole environment as a resource for exploitation. Geology, geomorphological evolution, agriculture, animal husbandry and mineral exploitation are discussed in detail. The mineralogical studies include reference to millstone extraction, Hellenistic and Roman mining of sulphur and other minerals, and a detailed account by R. Torrence of the celebrated obsidian sources. Her statistical analysis of waste and worked pieces indicates unsystematic exploitation of the sources, with no evidence that Phylakopi controlled an Aegean market economy in obsidian.

Other contributions examine settlement distributions, forms and history (together with an excellent site gazetteer by Cherry), and the changing impact of autonomy and external control on the Melian populations. There is some fine topographical work by Cherry and Sparkes on the Classical town of Ancient Melos. Wagstaff has a most informative chapter on the relations of mediaeval Melos with the outside world, with invasion maps of Arab and other raiders worthy of a central European *Völkerwanderungatlas*. The same author and S. Augustson examine traditional land use in the island; their interesting data for plot distances and journey times from farms and homes suggest controlling factors specific to Melos, or at least in contrast to those for Crete and Messenia. It would have been helpful if the land-use questionnaires had been included in the book, though the authors do provide much statistical information on the calculation of labour intensity coefficients for agriculture. The text throughout is supported by an extensive range of maps and tables.

Today all this is expected of such a project in early Aegean cultural studies. The account of the University of Minnesota's work in Messenia, *The University of Minnesota Messenia Expedition: Reconstructing a Bronze Age Regional Environment* (1972), is a magnificent predecessor. Current work in the southern Argolid and in Boeotia by American and British teams respectively is on similar, large-scale, multidisciplinary lines.

But here all comparisons stop. The present volume is *sui generis* in Aegean studies. It has a character and purpose far beyond the achievements of the studies so far referred to. The guiding inspiration is Professor Renfrew's. The purpose is not simply environmental reconstruction and explanation of state formation and disaggregation through time; rather it is to use Melos as an instance of the general processes affecting modes of state formation. So the character of the book is largely theoretical, deploying a wide range of models to investigate the central aim.

The living past on Melos — threshing the harvest in the traditional manner, using two donkeys to pull the threshing sledge (*volosyro*).

At times the text is not easy to follow: detailed modelling of the "intensification of subsistence production" in terms of the "production function" and "the incentive elasticity of labour input" are crucial concepts. A model of "socio-spatio-information hierarchy" for Melian state formation is discussed but rejected. So too are explanations based on irrigation, redistribution, secondary state status, importation of prestige goods and a temple-based system. The explanatory model that is chosen is one of "peer polity interaction". This answers well to *growth* in the economies and societies of the Aegean city states, growth through continuous economic exchanges between the states, from their differing resource bases. But I am not sure that it explains *initial* state formation. In Renfrew's final chapter the foundation of Classical Melos by Dorians emigrating from Lakonia, discussed earlier in the book, is strangely neglected.

My own view, which I am confident by no means all Aegean archaeologists will share, is that this book will have an important (and perhaps divisive) influence on future Aegean studies which attempt to go beyond the descriptive and try to tackle economic and social questions. It therefore merits long and serious study, even if one feels that what are proposed in the introduction as general propositions and hypotheses which "have dictated the final form of the book" seem either so general as to be unhelpfully obvious (resource potentials will support a range of population densities) or look rather like inferences after the fieldwork was done. But any big field project will develop its aims as it goes along; it responds to observed data. There is certainly no harm in that. ☐

Peter Warren is Professor of Ancient History and Classical Archaeology at the University of Bristol.

Politics, personalia and the past

Jonathan Tubb

Digging for God and Country: Exploration, Archeology, and the Secret Struggle for the Holy Land 1799–1917. By Neil Asher Silberman. Pp.228. ISBN 0-394-51139-5. (Knopf: 1982.) $16.95.

THERE are many people whose radios never change from a station broadcasting popular music yet will avidly read books on the life of Vivaldi or the extra-marital affairs of Alban Berg and will derive great enjoyment from them. The point of making this statement is simply to emphasize that it is not necessary to be a Palestinian archaeologist, or for that matter an archaeologist of any sort, to appreciate Neil Asher Silberman's remarkable book.

Unlike other authors who have charted the progress of exploration in the Holy Land, Silberman has gone much further, not only chronologically by extending the story back to the exploration by Napolean Bonaparte's "Scientific and Artistic Commission", but also in manner of presentation. He has avoided a tedious procession of facts about who dug what, where, when, and what they found, and instead presents a series of fascinating insights into the various researches seen in the context of the prevailing socio-political situation.

For example, not only does the author describe in great detail the complicated events which followed the discovery of the Moabite stone, events which finally led to the tragic destruction of the monument, but adds a new dimension by setting the whole sad saga against the backdrop of the equally intricate international relations among Great Britain, France and Germany just prior to the Franco-Prussian war. The near frenzy which accompanied the desires of the various scholars to acquire this monument is explicable in terms of its outstanding importance. For the black basalt stela, discovered at the site of biblical Dibon, commemorates the successful attempt of Mesha, King of Moab in the ninth century BC, to liberate his country from Israelite domination. It was, therefore, one of the first and most spectacular examples of an ancient inscription corroborating a biblical narrative, for the same events, albeit with a changed nationalistic bias, are recorded in the Second Book of Kings (II 3: 4-27).

So too, Silberman helps us to understand that the series of really massive excavations conducted by the *Deutscher Palästina Verein* during the early years of this century, e.g. Sellin at Ta'anach, Schumacher at Megiddo, and Sellin and Watzinger at Jericho (Carl Watzinger was the co-director at Jericho, not Schumacher as stated by Silberman), were conceived as part of a deliberate German policy to support and strengthen the failing Ottoman Empire as a buffer against its fragmentation at the hands of the British, French and Russians.

Ultimately, however, this is a book of personalia and Silberman paints vivid, if not always flattering portraits of many of the giants of the subject. Charles Clermont-Ganneau, the brilliant French archaeologist and scholar, comes off worst, depicted as the sort of man to whom one would not tell the time of day for fear of it being denied and ridiculed in the *Times*. In contrast the author gives a sympathetic account of the rather pathetic antiquities dealer, Shapira, whose almost certainly genuine "Dead Sea Scroll" fell prey to the same Clermont-Ganneau, an experience which was to lead eventually to the poor man's suicide. Even some of the best forgotten exploits are enthusiastically remembered by Silberman, such as Seetzen's ill-prepared and disastrously executed survey of Eastern Palestine or Montague Parker's outrageous search for the treasure of Solomon beneath the Dome of the Rock in Jerusalem.

Frontispiece of C. Conder's *Tent Work in Palestine* (1878)

Much attention is rightly given to the outstanding and pioneering work of the Palestine Exploration Fund. It was this organization more than any other which changed the course of exploration in the Holy Land, removing it once and for all from the hands of the wealthy dilettante and firmly establishing it as an academic and scientific discipline. Today, Palestinian archaeology is the most sophisticated of all the branches of Near Eastern archaeology, with refined stratigraphic excavation techniques and pottery chronologies capable of differentiating between periods as little as 50 years apart. Silberman successfully shows how the groundwork for these achievements was laid: ironically perhaps, two of the great innovators, Sir Flinders Petrie and George Reisner, were "borrowed" from Egyptology.

Relevant and interesting illustrations have been chosen to accompany the text, and the map showing the location of the various late nineteenth and early twentieth century excavations is a most useful adjunct. Altogether, this is an excellent book which can be recommended to both specialist and non-specialist. For students of Near Eastern archaeology, it must be placed in the category of essential reading.

Jonathan Tubb is a Research Assistant in the Department of Western Asiatic Antiquities at the British Museum, London.

Variations on the theme of cartography

Sarah Tyacke

Early Thematic Mapping in the History of Cartography. By Arthur H. Robinson. Pp.266. ISBN 0-226-72285-6. (University of Chicago Press: 1982.) $35, £24.50.

OPEN any atlas today and the chances are that many of the maps you see will be thematic, that is they show the distribution of some particular phenomenon stretched across a base map. The themes may range from the physical structure of the world to any aspect of human life, including abstract concepts; they are mapped by a number of graphic methods, immediately understandable by almost everyone, such as dots, flow lines, isolines and various types of tonal shading. These cartographical commonplaces were rarely, if at all, in evidence before 1700 and only took off in the first half of the nineteenth century. Neither the idea of thematic mapping nor the techniques for doing it were widely disseminated in intellectual and other educated circles of earlier times.

As the result of many years of research, A.H. Robinson has recovered the history of thematic mapping and vividly recounted its tender early years and its remarkable flowering under the impact of official and other statistical gathering from the end of the eighteenth century onwards. Unlike the general history of cartography, Robinson has few predecessors in this field and has provided *ab initio* the framework into which the maps gleaned from the works of statisticians, medical doctors, geologists, administrators and others may be slotted.

Although such maps are now very much the province of geographers and allied professionals, the earliest maps, so termed, were more usually drawn to illustrate or to analyse particular distributions or correlations between phenomena and the countries concerned by specialists in other fields; as such the maps are not to be found in atlases but are attached to official reports and professional papers, and illustrate a variety of subjects. For example, medical statistics on cholera were transformed graphically by Dr John Snow in 1855 to demonstrate the relationship between contaminated water supplies and the disease in London: it is these types of maps that Robinson describes and illustrates in the book.

Robinson has felt obliged to narrow his view of thematic mapping, however, to what he regards as the thematic map *sensu stricto*:

> ideally the thematic map has as its purpose the display of the overall structure or meaningful character of a distribution rather than simply showing where some things are.

In so doing — and additionally because he does not see some classes of thematic map as contributing to the development of graphic means of representation of data on maps — a number of types of thematic maps are not considered: for example, land use maps and other categories which may perhaps be called "special purpose" maps are not included. In the latter grouping might be mentioned such items as military plans, road maps and ecclesiastical maps. These types may or may not differ in graphic representation from that found on topographic maps but their function is primarily for a specific purpose and often illustrates a theme. In the case of ecclesiastical mapping a typical thematic example would be an atlas describing the numbers and distribution of properties owned by the Capuchin monks dated 1712. A key to the numbers of monasteries, priests, monks and lay brothers accompanies each map. The idea of representing the numbers by some manner of proportional symbolism is not present but the thematic element is quite obvious in this type of map.

Although it would indeed seem to be the case that the introduction of various thematic maps and symbols did not, as Robinson shows, occur before the end of the seventeenth century, it is perhaps unwise to assume that no one had previously conceived of the idea of depicting the structure of one phenomenon on a map. Certainly such an idea was not at all common but it is evident, even from some sixteenth century texts and maps which survive, that at least some people came close to the idea; for instance Queen Elizabeth I's minister William Cecil drew a map of the south-west of England and Wales showing the distribution of copper and lead mines in the 1570s. If one can see in this and similar attempts appreciation of some of the practical uses of such mapping, it must also be admitted that these maps show the qualitative location of phenomena rather than their quantitative distribution. It is quantitative mapping and its methods of representation which, as Robinson rightly points out, only emerge in the first half of the nineteenth century as a response to statistical studies.

The book is completed by 110 illustrations, many coloured, which are for the most part models of reproduction. In particular the selective use of legible detail rather than the reproduction of entire maps, which are so often indecipherable, is most welcome. Beyond this the great value of Robinson's work is that he has not only found a great many examples of thematic mapping, however defined, across a wide spectrum of professional endeavours, but has then produced a convincing and illuminating history which may be truly regarded as seminal. ☐

Lamarck the Mythical Precursor
A Study of the Relations between Science and Ideology
by Madeleine Barthélemy-Madaule

Translated by Michael Shank, this book presents a highly readable account of Lamarck's theories and the debates they generated. He emerges as a bold and intellectually adventurous pioneer whose early work centred on meteorology and botany and who became the leading authority of his period on invertebrates The author does not attempt to rehabilitate Lamarck, but shows that his theories are still relevant to the debate on innate versus acquired characteristics. November 1982, £12 25

When the Snakes Awake
Animals & Earthquake Prediction
by Helmut Tributsch

Tributsch has collected and evaluated reports on 78 earthquakes from ancient times to the present, covering a broad geographic and cultural range His book describes the unusual behaviour of animals in the minutes, hours or days before an earthquake struck: some of these connections, long dismissed as folklore, have been confirmed in the scientific literature of the 1970s. Tributsch presents an hypothesis to account for conditions that might trigger abnormal animal behaviour before an earthquake, and reports on such other premonitions as clouded springs, strange fogs, and enigmatic luminous phenomena Translated by Paul Langner November 1982, £14 00

Science & Technology Centers
by Victor J Danilov

Science and technology centres alive with moving gears and levers, activated computers and meters, flashing strobes and lasers, and other participatory exhibits, are designed to explain scientific concepts and technological artifacts This book, by the president and director of the Museum of Science & Industry in Chicago, consists of practical advice from an enthusiastic promoter of the concept, illustrated with numerous examples of successful programs initiated by centres throughout the world November 1982, £28.00.

Abusing Science
The Case Against Creationism
by Philip Kitcher

" . . a readable overview of modern evolutionary theory, of the facts that support it, and of the various points of scientific controversy However, his main effort is to examine and refute the creationist argument in detail. Readers . may want to follow up some of the extensive references the author gives to creationist literature I doubt, however, that this would do more than reinforce the author's conclusion." — *Christian Science Monitor*
October 1982, £10.50.

Nature's Second Kingdom
by Francois Delaporte

"[Delaporte's] project is to chart the concepts and practice of 18th century discourse on 'vegetality' . . He shows how these were related to questions about the nature of life and, most important, he argues that the epistemological standards of knowledge about plants was *animal* physiology." — *Annual of Science.* Translated by Arthur Goldhammer May 1982, £14.00

Genetic Alchemy
The Social History of the Recombinant DNA Controversy
by Sheldon Krimsky

This book offers a probing analysis of the setting for the rDNA debates, the postulated biohazards, the risk assessment process, the politics of science and regulation, and the means through which biologists protected their discipline October 1982, £17.50

Changing visions of an ancient society

Arthur A. Demarest

Ancient Maya Civilization. By Norman Hammond. Pp.337. Hbk ISBN 0-521-24017-4; pbk ISBN 0-521-28399-X. (Cambridge University Press/Rutgers University Press: 1982.) Hbk £22.50, $27.50; pbk £7.95, $12.95.

A MILLENNIUM ago the dense Peten jungle of Central America swallowed up many of the sprawling cities of the ancient Mayas, entombing their lofty temples, elegant palaces and graceful sculptures beneath a blanket of vegetation. During the past century and a half archaeologists, scholars and adventurers have spent much of their lives trying to unravel the mysteries of this lost civilization. *Ancient Maya Civilization* by Norman Hammond of Rutgers University is the most recent presentation of their findings and of our understanding of ancient Maya history and culture.

The Maya-speaking Indians of eastern Mexico and northern Central America have a heritage that can now be traced back for over 3,000 years. It was, however, the Classic Period (AD250 to 900) that witnessed the florescence of Maya culture — leaving a legacy of hundreds of archaeological sites in the jungles of northern Guatemala, Belize and the Yucatan peninsula. During this golden age, great centres such as Tikal, Palenque and Uaxactun flourished in an environment which appears utterly inhospitable to European and North American eyes. The hallmarks of this period are its fine masonry architecture, monuments sculptured in delicate bas-relief, raised stone roads and polychrome-painted ceramics whose beauty rivals the vase painting of Classical Greece. The sophistication of the Classic Period of Maya culture can be seen in its fully developed writing system, only partially deciphered, which records calendrical calculations and astronomical knowledge of astonishing accuracy — all based solely upon relentless non-telescopic observation and recording. Despite these cultural achievements, the great jungle cities of the southern zone of Maya culture were abandoned some time about AD900. Archaeologists have suggested various causes for the fall of the southern lowland centres including invasion, disease, ecological mismanagement, peasant revolt or complex combinations of such factors. Yet no consensus has been reached and this collapse remains a great mystery.

Hammond's *Ancient Maya Civilization* could not be more timely, since it comes fast upon the heels of a revolution in Maya archaeology. For half a century, scholars have understood the general nature of the Maya intellectual achievements. These have been beautifully described in the classic works of great Mayanists such as J. Eric S. Thompson and Sylvanus Morley. However, we can now see that these scholars misunderstood many fundamental aspects of Maya culture. The Maya were characterized as isolated, peaceful, theocratic societies supported by small populations of peasants using simple slash-and-burn agriculture and governed by priests concerned only with the worship of time and with astrological lore. Hammond's book incorporates the most recent research on settlement, agriculture and hieroglyphics, which shows Classic Maya society to have been far more dynamic than previously believed. Breakthroughs in hieroglyphic interpretation have revealed that the Classic Maya political landscape consisted of petty lords battling for control of regional city-states. Meanwhile, large-scale archaeological surveys have uncovered complex agricultural systems — raised fields, canals, terracing and other means of water control — which supported dense (proto-urban) populations.

Hammond artfully combines the knowledge gained by the early scholars with the most recent interpretations. First, he draws in the reader unfamiliar with the subject with dramatic, at times romantic, chapters on nineteenth-century explorations of the Maya ruins and twentieth-century archaeological projects. The following, more substantive, chapters on Maya ecology and cultural history are rendered accessible by numerous illustrations, maps and charts. The tone then shifts in thematic chapters on subsistence, politics and trade, in which Hammond presents the evidence for the new, more realistic, characterization of ancient Maya society. Yet in the subsequent accounts of Maya architecture, art and religion, he draws heavily upon the works of the early Mayanists with an undisguised admiration. Hammond also maintains a balance in his discussion of still controversial topics, such as specific interpretations of Maya dynastic history, foreign influences on the Maya and the causes of the Classic Maya collapse. In short, the author is surprisingly successful in integrating old and new conceptions of the ancient Maya.

The book, however, is less successful in dealing with the regional diversity of the civilization. Hammond himself is an active field archaeologist, excavating in Belize, and his text reflects a regional bias towards the southern, lowland manifestation of Maya culture. In the chapter reviewing the rise and fall of Maya civilization, he gives only the most superficial treatment of the development of the great centres in Yucatan, the Guatemalan highlands in the south, and the south-eastern frontier in El Salvador and Honduras. In the thematic chapters, Hammond similarly draws most of his examples from the same handful of sites in Belize and the southern lowlands. Students and laymen reading Hammond's outline of Maya history also should be made aware that his very early datings for the beginnings and development of complex village societies in the lowlands (which I personally accept) are still being hotly debated.

These criticisms notwithstanding, the book is an excellent introduction to the ancient Maya. Indeed, even the author's research biases, when combined with his crisp journalistic style, help to convey the fluid nature of Maya archaeology in which interpretations are undergoing constant revision as each excavation unearths new contradictions and fresh controversies. Hammond's book achieves a unique fusion of a reverence for the early archaeologists and explorers with an insistence on the most current interpretations. It is a perspective which gives the reader a new vision of both this lost civilization and the volatile discipline that is rediscovering it.

A ring of irony

J.W. Cornforth

The Enchanted Ring: The Untold Story of Penicillin. By John C. Sheehan. Pp.224. ISBN 0-262-19204-7. (MIT Press: 1982.) $15, £10.50.

IN 1941, when Howard Florey's team at Oxford had demonstrated the value of penicillin for treating bacterial infections, it became imperative to find better ways of producing the drug in quantity. A huge cooperative effort by 39 industrial, university and government laboratories in the United Kingdom and United States explored not only the existing method of fermentation, but also the chemistry of penicillin in the hope of producing it by synthesis if fermentation techniques could not be improved. Research on the fermentation process was brilliantly successful, and the problem of producing penicillin was solved. In contrast, although the chemical effort succeeded in finding out the structure of penicillin it failed to find an efficient method of synthesis.

As the urgency of the problem faded, chemists engaged on the synthesis of penicillin turned to other work. The most notable exception was John Sheehan, of Max Tishler's team at the Merck laboratories. Leaving Merck for the Massachusetts Institute of Technology after the war, Sheehan sought a rational synthesis of penicillin and in the end he found one. His book is partly an account of his personal involvement with the penicillin problem and partly an anecdotal story of the drug's discovery and development. It is difficult to picture the readership at which Professor Sheehan is aiming; but the book will certainly interest, and probably irritate, all those who have worked on penicillin.

Sheehan's account of the early days of penicillin reads largely as an attempt to magnify Fleming's contribution at the expense of Florey's and Chain's. He throws no new light on this old controversy. More novel is his account of the organization behind the research and production effort in the United States in 1941–1944. He draws here on minutes of the US Committee on Medical Research, and other official papers. He has recorded on tape the reminiscences of some principal participants, notably Karl Folkers, and he reproduces extracts from these, along with an account from Hamao Umezawa of a belated Japanese effort to produce penicillin in 1944–1945. The absence of chronological order makes difficulties for the reader, especially in a book so obsessed by priority and credit. The difficulty persists throughout.

The part of the book dealing with chemistry is in many ways the most disappointing. Chemists are likely to be put off by the unexpectedly poor appearance and layout of the diagrams, and by oversimplification that sometimes sacrifices truth, whilst the non-chemical reader may well be confused and misled. This is particularly true of the chapter where one would expect it least — the description of Sheehan's own work. A brief account, based less on the book than on the scientific literature, seems indicated here to make clear Sheehan's contribution.

The molecule of penicillin is relatively small and simple, and the difficulty of synthesis arises mainly from the presence of several reactive groupings that cannot easily be manipulated without mutual interference. It was already recognized by the end of 1943 that pencillin is an anhydride of penicilloic acid, a substance easily made from penicillin and easily synthesized. A decision between two possible structures for this anhydride was eventually made in favour of the β-lactam structure, but it was found to be impossible to produce this from penicilloic acid or its simple derivatives. That was the problem that Sheehan solved. His earlier successes were obtained by making inert analogues of penicilloic acid that enabled him to use a quite vigorous reagent — thionyl chloride — to close the strained β-lactam ring. The breakthrough came when he discovered that carbodiimides could be used to form amides in mild conditions from carboxylic acids and amines; a most valuable peptide synthesis arose from this finding. The cyclization of penicilloic acid to penicillin is a special type of internal peptide synthesis, and when the carbodiimide method was applied to a suitable penicilloic acid a natural penicillin was formed in low yield. This work was submitted for publication in February 1957.

Sheehan's method for synthesizing penicilloic acids proceeded by way of an analogue lacking the acyl side-chain characteristic of penicillins. He tried the long shot of cyclizing this compound and obtained a crude mixture containing a very small proportion of racemic 6-aminopenicillanic acid (penicillin without the acyl side-chain). When this mixture was treated with an appropriate acyl chloride, formation of a penicillin could be shown to have taken place. Sheehan did not publish this experiment but he applied for a patent on it, in March 1957. In 1959, he modified the process by using a trityl group to protect the reactive amino group before cyclization; he then obtained much better yields in closure of the β-lactam ring, though the yields from subsequent removal of protecting groups were poor. This procedure gave him fully synthetic 6-aminopenicillanic acid.

In 1957, workers at the Beecham Laboratories isolated 6-aminopenicillanic acid in pure form by fermentation. This completely independent discovery was the basis for an enormous development of "semi-synthetic" penicillins carrying "unnatural" acyl side-chains. That whole development rests on aminopenicillanic acid derived from fermentations and no penicillin has been produced in commercial quantities by total synthesis. Nevertheless, Sheehan's commercially valueless procedure enabled him to gain, after a protracted legal battle, priority of invention. The last chapter in his book describes that battle.

Sheehan's achievement in making a total synthesis of penicillin was a splendid piece of work. His book, in contrast, lends its own sub-title — *The Untold Story of Penicillin* — a ring of irony. ☐

Sir John Cornforth is Royal Society Research Professor at the University of Sussex. He is a part author of The Chemistry of Penicillin *(Princeton University Press, 1949).*

Elks, Whelks, and their Ilk

The monarchs of the Irish bogs
Succumbed to neither men nor dogs
But (most ecologists agree)
To calcium deficiency.
They scoured the base-deficient peat
For antlers and old shells to eat
And, finding all too few, they died
Around the Celtic countryside.

. . .

Then mourn the passing of the elks,
But note the wisdom of the whelks
That roam the shore — their
native heath
With silver-indurated teeth
And bore to death their mollusc friends,
Who come to sad, unsuccoured ends.
Without the need for gins and limes,
The whelks survive to modern times.

. . .

Thus ungulate and gastropod,
And all that live by sea or sod,
Are doomed to be — or not to be
By biogeochemistry.

Ralph Lewin

Children of clay?

N.W. Pirie

Genetic Takeover and the Mineral Origins of Life. By A.G. Cairns-Smith. Pp.477. ISBN 0-521-23312-7. (Cambridge University Press: 1982.) £15, $29.50.

Eminent physicists have written so much cocksure balderdash about the nature and origins of life, that it is reasonable to be apprehensive about a contribution to the subject from a chemist. We have become accustomed to the naive assumption that, because life is now dominated by the behaviour of proteins and nucleic acids, a study of the conditions necessary for their probiotic synthesis and interaction is relevant. (If that assumption were valid, the right approach to the history of the use of fire would be to study the mechanism of a cigarette lighter, and a study of the composition of paper and ink would illuminate the history of writing.) Cairns-Smith argues instead that proteins and nucleic acids were successful late arrivals on the biological scene. This is an unpopular, but not wholly novel, point of view — a few of us have been adumbrating it for many years. What is novel is that he suggests a concrete alternative hypothesis, almost literally concrete because he gives silicates a fundamental role.

The argument is that clay minerals are not simple rock fragments, but are recrystallized structures with a final form which depends on the conditions of crystallization, the extent to which supersaturated solutions are seeded and the transmission of accidental defects. The last point will be the most controversial. An evolving quasi-biological system needs a genotype and phenotype: this is the old distinction between form and substance. In biology, contrary to Aristotle's dictum, it is the form, the genotype, that lasts and not the substance.

About a quarter of the book is occupied by a description of the immense variety of clay minerals, the distortions and defects in them, and their behaviour in the presence of other substances. The photomicrograms and electronmicrograms show complicated folded laths and other structures, colourfully described as "micro-origami", "card houses" and "a self-assembling maze". Even without the detailed and plausible argument which is presented here, the structures shown in these illustrations support the idea that, if prevital evolution happens anywhere, this is a reasonable group of substances within which to search for it. The old analogy between life and crystallization, which was discussed by Kant, Reil, Troland and others, may now legitimately be elevated from the status of analogy to that of hypothesis. Nevertheless, it may be argued that the mechanism suggested — for example a particular type of clay crystal perpetuating its ability to thrive in crevices in sandstone by shedding "seeds" into neighbouring crevices — is rather remotely connected with what we normally regard as life. That objection applies with equal force to the organic polymerization picture which has recently become conventional. Neither picture fills the gap between the never living and the nearly living in a wholly satisfactory manner. But it is pleasant to have a change of outlook.

Cairns-Smith chooses clay minerals as the vehicle for biopoesis because of their versatility and indubitable abundance on the probiotic Earth. However, evidence from meteorites, and from *in vitro* experiments going back to the time of Berzelius and Berthelot, make it equally certain that tars would also be present. Tars are the main product of the tediously repetitious experiments in which gas mixtures, made up according to constantly changing opinions about the composition of the probiotic atmosphere, are now exposed to various types of energetic insult. Tars are mentioned here several times. They are invariably disparaged as inert end-products or as "tarry chaos". I have been arguing for many years that sunlit tar is as likely a site as any other for an early stage of biopoesis, but after reading this book I would include clay minerals in the notional mixture and, following Goldschmidt, some minerals containing the transition elements. Everyone to his taste. Cairns-Smith is a clay enthusiast: he enjoys giving clay a role more dynamic than mere adsorption and sequestration.

There is no suggestion here that clay filled this dynamic role in the hypothetical eobiont any better than protein would have done. On the contrary, there is the explicit statement: "Anything clay could do organic molecules would eventually come to do better". To quote again, the discussion is said to be about: "What was biochemistry like when protein was an optional extra?". Several passages emphasize the point that eobionts need not have been small. The idea that life started small presumably stems from a fallacious conflation of early life with viruses. Being obligate parasites, viruses have obviously nothing to do with the case: it is not even useful to classify them as organisms. It is only when competition with other organisms puts a premium on rapid reproduction that smallness becomes advantageous. In the beginning there was no competition. As Cairns-Smith puts it:

> The microscopic size of the modern bacterium should be seen as one of its most notable achievements rather than any sign of evolutionary infancy. The bacterium is a highly concentrated package of ingenuity.

If minerals have the potentialities attributed to them here, it should be possible to demonstrate processes comparable to evolution taking place among them now. This point is discussed briefly with references to some as yet unconfirmed claims that such processes occur in various precipitates. It is not enough to show that there are progressive changes in these precipitates; to be convincing it should also be demonstrated that the change is hastened when a fresh precipitate is inoculated with a "seed". The absence of evidence for this does not invalidate the hypothesis. About a gillion (10^9) years seem to have elapsed between the time when physical conditions on Earth became comparable to those with which we are familiar, and the formation of the first organisms. Relevant *in vitro* processes need not therefore be rapid.

Evidence that the first organisms were inorganic could also come from an appraisal of the present-day biological role of minerals. Some organisms show great enterprise in exploiting specialized properties such as the magnetism and hardness of Fe_3O_4 and the density of $BaSO_4$. It has been suggested that the five-fold symmetry of most echinoderms is imposed by the 75° angle between the faces of calcite crystals, and it may be legitimate to wonder whether the greater intracellular importance of K rather than Na is a relic of the behaviour of these ions in clays. On the whole however, such typical mineral elements as Al and Si seem to have been steadily eliminated. It is primitive plants that make most use of Al, and primitive animals of Si — though there are still substantial amounts, with obscure functions, in the human body. Clearly, evidence for a mineral background to biology is tenuous: the postulated takeover is nearly complete. We are, on the whole, reasonably satisfied with the result. Sir Walter Scott's words are apposite and partly justify the title of this review: "Well hast thou done, frail child of clay!".

Recent articles and letters to the Editor of *Nature* have shown that there is disagreement about the principles that operate and have operated in evolution. The theme often crops up in this book. At a time when we are still arguing about the survival value of many queer features in living organisms, some of the statements made have a rather over-confident tone. It will be interesting to see what comments on that aspect of Cairns-Smith's thesis are made by reviewers with a primary interest in evolution rather than chemistry. Cairns-Smith is commendably tentative, he recognizes that a crystalline gene might not work and says that: ". . . when we are near to the answer we will find many similar answers, and so we will not be able to say exactly how life must have started on Earth". He writes clearly with many neat phrases and some humour. The result is an excellent book — the most plausible and sensible that I have seen on the subject. □

N. W. Pirie was formerly Head of the Biochemistry Department at Rothamsted Experimental Station, Hertfordshire. He has been writing articles on the nature and origin of life since 1937.

How to get the wind up in the future

F.J.P. Clarke

Wind Energy for the Eighties: A Review by Members of the British Wind Association. Pp.372. ISBN 0-906048-73-7. (Peter Peregrinus: 1982.) £19.50, $49.50.

Is wind energy a credible source of electricity for the world, and in particular for the UK? *Wind Energy in the Eighties*, a status review written by experts from the British Wind Energy Association, gives a clear answer: wind energy could readily contribute 20 per cent of the UK's electricity supplies and it could be well on the way to that by the year 2000. How valid is that claim?

Although detailed resource surveys have still to be carried out both on land and offshore, the book explains why resource size is unlikely to be a limitation. Because the wind is an unreliable source of power, our electricity system is limited in what it can accept to perhaps 20 per cent of total demand. But that much at least the Electricity Boards agree can be accepted; and since the feasible resource base is likely to be much greater than that, resource size is unlikely to be limiting — provided, that is, the economics are right.

There are two aspects to this latter question, the value of wind power and its cost. Because of the unreliability of wind power, its value must be judged primarily in terms of the conventional fuels it displaces when the wind is blowing, which depends on the plant mix — how much coal or oil will be saved? And that depends on how many wind machines are in the system; the more wind machines there are, the smaller is the value of the next machine to come on stream because the highest running-cost conventional plant will always be displaced first. Modelling such system economics is difficult; present models may be inadequate, and the fact that one is concerned with a plant mix well into the future adds to the difficulties. Nevertheless estimates can be made and are given in the book, assumptions being clearly stated.

The second aspect of the economics is the cost of the wind machines themselves and their associated plant. Here, overseas estimates tend to come out lower than those made in the UK. While this may in part be the problem of relating US dollars or Swedish kroner to British pounds, the book does point up differences in technical assumptions that also contribute.

From all these facts, speculations and assumptions the balanced conclusions emerge that wind machines can be integrated into the electricity grid in substantial numbers, and that in some cases it should be economically worthwhile to do just that.

If these conclusions seem modest against the claims sometimes made for wind power, it should be remembered that they are formulated by professional scientists and engineers who are as aware of the uncertainties as of the very real promise of the technology. More knowledge is needed to lower costs and encourage adoption of the technology, especially offshore.

One of the important concepts behind the possibility of lowering costs is the compliant structure. The design approach in the UK has so far been based upon structural stiffness to avoid resonance and vibration which are notoriously difficult to predict, and which can be so damaging. Such thinking was also behind the earlier US designs. However, subsequent US, Swedish and German designs have gone for a more compliant structure. This involves a much better understanding of the dynamics of the whole structure so that lighter, smaller and less-expensive components can be used. The dynamic forces can then be absorbed with compliance rather than with stiffness. As is admitted in the book, this approach is rapidly gaining favour as an important way to reduce costs, though the extent to which the concept can be applied in the highest wind regimes in the UK has still to be determined. However, as reflected by the cursory treatment, the UK is lagging in this area.

Wind Energy Group

The shape of wind machines to come — an artist's impression of the wind turbine to be built on Burgar Hill, Orkney, by the Wind Energy Group. Overall the structure is 75m in height, taller than Nelson's Column in London.

Two basic types of machine are being developed industrially in the UK and both receive good coverage together with their overseas counterparts. The horizontal axis machine had the earlier start, and this has been followed by the vertical axis concept. The rotor blades of horizontal axis machines are subject to reversing gravitational loadings as they turn, thus making them the components most at risk from fatigue failure. The vertical axis machines avoid this and have the additional advantage of being omnidirectional; however they would be more prone to other problems which need investigation.

At megawatts size either machine would look large alongside the traditional windmill and could reach higher than the largest electricity pylons, thus raising the problem of visual amenity. Also, there have been reports from the United States of television interference, windows rattling and other environmental impacts; but so far they seem to be rather isolated events. On this type of issue, as on techno-economic issues, real answers will come only when large machines are up and working in the UK.

Such possible environmental problems make it attractive to place machines in shallow waters offshore. This would cost more, but, it is claimed, expense may be outweighed by the higher wind speeds and the environmental freedom to build bigger structures. Whatever these pros and cons, different practical and institutional advantages are also covered in the book. Wind machines of 1–10MW provide a modular power source that can be added to the system quickly as needed, without all the well-known problems of massive construction projects. In addition, it is pointed out that such machines could provide the beginnings of decentralized power supplies — a possibility that could attract support across political boundaries.

Wind Energy for the Eighties brings together professional views from the academic world, from industry both public and private, from research institutions and from countries overseas. Apart from its value as a status report, the book sets out simply and clearly the background theory to many of the topics. Students and those new to wind energy will find it as good a source book as those already in the field. It is a pleasure to welcome it.

F.J.P. Clarke was Chairman of the National Wind Energy Steering Committee until 1981. He is now Director of Strategic Studies at the United Kingdom Atomic Energy Authority.

Cornucopian faith

Eric Ashby

Catastrophe or Cornucopia: The Environment, Politics and The Future. By Stephen Cotgrove. Pp.154. Hbk ISBN 0-471-10079-X; pbk ISBN 0-471-10166-4. (Wiley: 1982.) Hbk £16, $35; pbk £6.95, $15.30.

OVERHEARD in a pub, two women talking: "She was as stubborn as a mule. But I was just as firm". This is the theme of Professor Cotgrove's book: the controversy between those he calls catastrophists and those he calls cornucopians, those who predict a collapse of industrial society and those who believe that threats to our survival will continue to be kept at bay by the very products of that society. Each side so sure it is right and so ready to dismiss the other side as irrational. Each side having access to the same set of facts but interpreting them so differently.

Professor Cotgrove is a sociologist who believes in using quantified data prepared from questionnaires for an analysis of what a layman would call "public opinion" on environmental issues. His aim is to discover what sort of people are catastrophists, and what sort cornucopians. He wisely discards these picturesque (and in my view misleading) labels for more specific categories: environmentalists (a sample of 576 persons from the Conservation Society and the Friends of the Earth), industrialists (a sample of 400 from *Business Who's Who* and *Who's Who of British Engineers*), trade union officials (399 names from the *Trade Union Handbook*), conservationists (500 names from the World Wildlife Fund, UK Branch), and, to represent the public, 1018 names drawn from the electoral registers of Bath, Oldham and Swindon. These people were asked to respond to a battery of questions about their attitudes to the environment, to various other social issues, to the effectiveness of the present political system, to the morality or otherwise of the imperative of economic growth. With this background of information Professor Cotgrove pursues his aim, concentrating largely on environmentalists on the one hand and industrialists on the other.

The initial results cannot be described as surprising: 92.4 per cent of environmentalists consider environmental problems to be "extremely" or "very" serious; only 45.9 per cent of industrialists share this view. Each category of the public behaves predictably. The environmentalists were selected from a sub-group which has deliberately carried its campaign into politics; belief is often hardened into ideology. Conservationists are milder people, less politicized, inclined to give a higher priority to law and order and to the economy than they do to environmental issues (except the conservation of the species to which they are attached: birds, or whales, or redwoods). Industrialists naturally put their faith in the creation of wealth and tend to underplay anything that threatens that faith. Trade union officials find themselves, as one would expect, sitting on the environmental fence. Of course they want improved social conditions, less pollution, public finance for environmental tasks, but when it comes to jobs versus the environment one doesn't need Professor Cotgrove's statistics to provide an answer.

After this somewhat pedestrian start the book gathers pace. Environmentalists and industrialists emerge as the personifications of two opposing life-styles which Professor Cotgrove (unwisely, I think, for it begs the $64 question in the book) calls "paradigms". The typical environmentalist is in early middle age, well educated, engaged in what industrialists would call a non-productive occupation (as teacher, social worker, academic, doctor), left wing in politics (unlike conservationists, who are commonly right wing), hostile to the current enthusiasm for economic individualism and commitment to economic growth. The typical industrialist in the sample is over 40, also well educated, engaged in production or marketing of commodities, right wing in politics and living — except in his home life: the book makes that distinction — by the strenuous survival standards of the market place.

In this crude classification some truth, of course, is lost. If environmentalists and industrialists were victims of their respective paradigms there would be no cross-fertilization of ideas between them. It's not as bad as that. It was the industrialist who successfully flooded Latin America with mass-produced automobiles, Aurelio Peccei, who founded the Club of Rome and has become the high priest of environmentalists. So not every reader will agree with Professor Cotgrove when he says:

> Industrialists and environmentalists . . . inhabit different worlds. From where they each stand, the world looks different. What is rational and reasonable from one perspective is irrational from another.

It is a caricature, but the merit of caricatures is that they do carry some truth. It is not necessary to swallow the whole of Professor Cotgrove's thesis in order to get from him some useful, if uncomfortable, ideas. The idea that strikes me as most important is the suggestion that the issues environmentalists get so worked up about — acid rain, nuclear waste, lead in petrol, draining of wetlands — are symbols of a much deeper rejection of the social order that finds it fitting to exploit the environment in these ways. Accordingly, though the industrialist and the environmentalist might agree on the desirability of taking lead out of petrol, they would act for totally different reasons: the one, out of expediency, the other as a step toward ridding the air of a moral, as well as a material, impurity. The book quotes the well known work by Mary Douglas on the anthropologist's concept of pollution; it might, even more appropriately, have quoted the traditional Middle English meaning of the word: "to render ceremonially or morally impure, desecrate, destroy the sanctity of. . .".

For this is what Professor Cotgrove is driving at: the idea that environmentalists are not out just to tidy up land, air and water (to do no more than that would be rejected as "cosmetic" treatment). They are out to overthrow the lifestyle that has, in their view, desecrated the countryside and de-humanized cities, and to put in its place what Illich calls "conviviality". A few years ago this sort of protest would have been academic in the pejorative meaning of the word. But a change has occurred that makes this protest potentially significant: it is the undeniable loss of confidence in the capacity of our political system to cope with our social and economic problems, a "decline in political legitimacy". To come back to Professor Cotgrove's statistics: it is not surprising that 74 per cent of environmentalists have little trust in political parties; it is surprising (at any rate, it ought to be) that 68 per cent of industrialists, too, have "little trust". And even more surprising that, when asked whether they support direct (extra-parliamentary) action to influence government decisions on environmental issues, there is still support from 23 per cent of the industrialists who responded to the questionnaire. The framework of consensus within which protest groups could easily be tolerated is showing ominous signs of weakness. Professor Cotgrove suggests (as have, of course, many others before him) that the change from industrial to post-industrial society may not be a smooth one. Indeed, if he is right to use the word "paradigm" for the ruling lifestyle and the challenge being made to it, then the two paradigms cannot co-exist (that is why I don't think "paradigm" is the best word to use). And the question becomes not "whether?" but "how?" the transition will take place.

It is at this point, at the end of the book, that the reader may wish Professor Cotgrove had carried him a bit farther. We have to be content with I'd call the Heilbroner formula: get your house in order by constitutional means, or you'll find the constitution swept away and replaced by Leviathan. The urgent need is for reflection on the kind of political institutions which might evolve, from what we have to what we need. In his book *Ecology and the Politics of Scarcity* (which Professor Cotgrove does not refer to) William Ophuls has made some suggestions which could be the prolegomenon to an environmental ethic. Sociologists have an important part to play in finding out how such an ethic could be disseminated among a people still living (as Professor Cotgrove puts it) under a "Cornucopian faith". □

Keeping nuclear weapons inside the club

Stephen M. Meyer

Controlling the Bomb: Nuclear Proliferation in the 1980s. By Lewis A. Dunn. Pp.209. Hbk ISBN 0-300-02820-2; pbk ISBN 0-300-02821-0. (Yale University Press: 1982.) Hbk $21, £16; pbk $6.95, £5.45.

Nineteen eighty two has been a fairly active year for watchers of international conflict. Britain and Argentina went to war over the Falkland Islands. The Iran–Iraq War flared to new levels of ferocity, culminating in the largest tank battles since the Second World War. Meanwhile, Israel engaged PLO and Syrian forces in Lebanon.

It is worth pondering how each of these conflicts might have evolved had they taken place in 1992, when many of the protagonists might have added nuclear weapons to their arsenals. What might have been the result of the detonation of an Argentine nuclear warhead in the midst of the British naval task force? What would have happened if the Iraqis, Iranians or both had nuclear bombs for their tactical aircraft? And imagine the effects of sudden demonstration by the PLO that it had acquired a nuclear weapon (by theft, purchase or gift). In fact, none of these is implausible, and unless we wish to see such items in future news headlines we must begin to take a more serious and systematic approach to coping with the problem of nuclear weapons proliferation.

It is in this context that Lewis Dunn's *Controlling the Bomb* makes several timely contributions to our understanding of the spread of nuclear weapons, the threats posed by further proliferation and the options for slowing its pace and scope. In what is, perhaps, the most important aspect of this book, Dunn discards two pernicious notions currently much in vogue: that nuclear proliferation is essentially a technological phenomenon, and that further proliferation may have benign — if not beneficial — effects.

The first notion has dominated the literature since the beginning of the 1970s. Nuclear weapons proliferation was seen as a genuine technological imperative, a deterministic outgrowth of the presence of nuclear power plants. Accordingly, the eradication of nuclear power technology (and associated plutonium stocks) was prescribed as the most effective approach to minimizing, if not eliminating, that threat. In reviewing events of the past decades, Dunn exposes the fundamental fallacy of this view. While technical difficulties have indeed been a factor in some cases of nuclear restraint, decisions to pursue — or abstain from — the acquisition of nuclear weapons have been driven by politico-military considerations. Efforts by Israel, South Africa, Libya, Iraq and Pakistan to acquire nuclear weapons cannot be explained by the corrupting influences of indigenous nuclear power generation because the former preceded the latter. Conversely, the failure of West Germany, Japan, Sweden, Switzerland, Canada, Belgium, South Korea and some two dozen other countries to produce nuclear weaponry cannot be accounted for by a lack of expertise. In either case, the total eradication of nuclear power technology would not affect these countries' long-term capability of putting together a nuclear weapons programme using indigenous resources.

As Dunn implies later, technical problems do play an important role in non-proliferation efforts simply by buying time. However, the effectiveness of technological constraints is undergoing continual erosion. Dunn points to the sources of trouble. In their rush to increase export revenues and markets, the primary supplier states have been backsliding on controls over sales of sensitive nuclear know-how and products. Grey and black marketeering have added to the flow of nuclear goods. Compounding the problem is the rise of third-tier nuclear suppliers — India and Argentina, for example. In the end the ability to produce nuclear weapons is inherent in the scientific, technological and industrial growth that is part of economic development.

While he does not see an inexorable drift towards the further spread of nuclear weapons, Dunn acknowledges that there are likely to be a number of instances where the confluence of technical expertise and political will produces new members of the nuclear club. Is there any reason to interfere, to try to alter the pace and scope of proliferation? Here Dunn confronts the second misconception. The presence of nuclear weapons, it is argued, can bring peace and stability to conflict-prone areas, such as the Middle East, by establishing regional deterrent systems similar to that which has prevented a US–USSR war for almost 40 years. Just as the porcupine can walk safely through the forest, so too can the small nuclear power dwell among a world of hostile countries. In explicitly rejecting such bizarre formulations, Dunn points to a host of factors that invalidate these analogies, while suggesting considerable threats ahead: the geographical proximity and political instability of those countries which may come to possess the bomb, superpower relations with such nations, and terrorist activities.

Recognizing the clear threat posed by the wider possession of nuclear weapons, the second half of *Controlling the Bomb* outlines a range of alternatives for a US anti-proliferation strategy. The first set of measures is aimed at checking the pace and scope of further proliferation. Dunn argues that — in order to buy time — technical barriers should be increased so as to make entry into the nuclear club as difficult as possible. Dunn notes that pilot-scale and research facilities can pose a greater threat of proliferation than full-scale commercial nuclear power facilities. Also, the United States should continue to limit the number of countries engaged independently in fuel reprocessing, while re-establishing itself as a reliable supplier of nuclear fuel. Multinational nuclear research and energy programmes (for instance to deal with international plutonium storage) should replace national projects, thereby giving developing countries access to advanced nuclear technology but without the risks associated with independent national programmes. Closing of technology export loopholes is necessary as well.

In order to affect relevant incentives and disincentives, Dunn also proposes a US strategy of political, economic, military and diplomatic sanctions. The objective is to impose such large drawbacks that they overwhelm any existing urge to acquire nuclear weapons. As Dunn emphasizes, this can only be accomplished through case-by-case analysis and direct intervention, not by some global or universal non-proliferation policy. In this respect, he notes — but, unfortunately, does not pursue in great detail — the fact that day-to-day US foreign policy does have an important effect on the balance of proliferation incentives and disincentives; for example the pursuit of other, frequently more important, foreign policy objectives may conflict with non-proliferation interests as often as they reinforce such interests.

A second set of measures is concerned with "limiting damage" in face of further proliferation. Dunn argues that there may be "natural" stopping points in the development of nuclear weapons — so-called proliferation firebreaks — behind which nations could be held by the threat of sanctions and other forms of diplomatic intervention. Where the drive towards the acquisition of a nuclear arsenal could not be prevented completely, emphasis could be placed on retarding the futher evolution of the budding, but still small, nuclear force. Some countries might be contained at the convert (untested weapons) stage (e.g. Israel); some at the PNE (peaceful nuclear explosive) stage (e.g. India); some at the small stockpile stage; and so on.

4th Superb Edition
Prescott & Dunn's
Industrial Microbiology
Edited by Gerald Reed
Vice President, Amber Laboratories USA

The up-to-date guide and reference tool to industrial technology and applications in the microbiology of foods and food ingredients – with a special section on biological production of fuel alcohol.

Macmillan Hardcover 896 pp £42.50
ISBN 0 333 33630 5 1982

Genetic Engineering/ Biotechnology Sourcebook

Never before published! Profiles of 1,529 recent and ongoing genetic engineering/biotechnology research projects funded by 122 US government and non-profit organizations.

Covers research affecting: ★ Pharmaceuticals ★ Medicine and Diagnosis ★ Agriculture ★ Food Processing ★ Energy ★ Chemicals.

Reveals for each project ■ Nature and objectives of research ■ Funding source and money awarded ■ Names and addresses of individual researchers.

Special Yellow Pages reference section – tells you at a glance who's researching what, where, when and how.

Macmillan Softcover 350 pp £52.50
ISBN 0 333 34148 1 1982

Lastly, the task of mitigating the consequences of nuclear proliferation is addressed. Dunn considers three thresholds to contend with: after nuclear weapons production is first detected; after a first nuclear test; and after nuclear use in warfare. An assortment of possible US responses is suggested. Technical assistance might be offered after the fact to reduce the dangers of unauthorized or accidental use. Security guarantees could be given to non-nuclear weapons states likely to be affected by the newly born nuclear power. Adjustments to alliance relationships may be required. And finally, consideration must be given to military intervention against a budding nuclear force that poses a clear threat to peace, or against one that comes under the control of non-governmental forces.

Dunn concedes that many of the policy options in each of these three categories of control conflict with one another. As a result, the possibilities for developing a coherent US non-proliferation strategy are quite small. Thus, the reader should not be surprised to find no single blueprint for ensuring a world in which nuclear-weapons are no more widely available than they now are. Controlling the bomb will require careful attention to decision-making in individual countries, and to the development of an approach to the problem that has the flexibility and versatility to tailor responses to the case at hand. Dunn deserves much credit for getting our thinking back on the right track. □

Bytes and pieces from an expert hand

Margaret A. Boden

Machine Intelligence and Related Topics: An Information Scientist's Weekend Book. By Donald Michie. Pp.316. ISBN 0-677-05560-9. (Gordon & Breach: 1982.) $55.

DONALD Michie has played a crucial role in the development of artificial intelligence (AI) in Great Britain. He was a moving force behind the first British AI department, set up nearly 20 years ago in Edinburgh and recognized as of world-class stature. His commitment and enthusiasm derives partly from his friendship as a young man with Alan Turing (a colleague at Bletchley during the Second World War), on whose work our understanding of computation is grounded. The experience at Bletchley was influential too in its emphasis on the applications and social context of science, and on the value of interdisciplinary cooperation in scientific research.

Michie's intellectual pedigree commands attention, and not surprisingly there are many nuggets of interest in his book. But this collection of papers is, overall, disappointing. It is an uneasy mixture, ranging from ephemeral two-page journalistic pieces, through accounts of AI aimed at the general reader, to technical discussions of chess programs and probability theory. It includes personal memoirs of Turing, advice to eminent scientists in danger of being seduced into administration and circuit-lecturing, and impassioned criticism of the Science Research Council's Lighthill Report — which seriously hindered the progress of AI in Britain a decade ago and from which the field has not yet recovered.

The examples of machine intelligence on which Michie concentrates are expert systems and chess programs. Expert systems are codifications of knowledge and inference about specific topics, such as geology or the diagnosis of infectious meningitis. The general interest of these is obvious, and his description of a variety of such knowledge-based systems (some of which are already in professional or commerical use) is lucid and informative. Chess programs might appear to be mere toys, but Michie argues that chess is especially well-suited to the experimental development of AI. It is a complex but relatively well-understood and clearly defined domain, and it demands research into techniques of heuristic search, pattern-recognition and inductive learning. AI work in other areas — such as language-understanding — is mentioned, but does not receive the detailed attention given to chess and expert systems.

Each paper in this collection was appropriate, even useful, in its original context. Michie is technically sophisticated, lucid in expression, historically sensitive and imaginative with respect to the future potential of AI. Few readers will find nothing of interest here. But it would be a strange person — even if he was that odd beast, an information-scientist — who would devote much of a weekend to reading this book. Despite Michie's advice that eminent scientists should spend their time doing innovative research rather than surveying their field, I hope he will one day give us what he is so well equipped to write: a sustained discussion of machine intelligence and its social context. □

Where are they now?

James S. Trefil

Contact with the Stars: The Search for Extraterrestrial Life. By Reinhard Breuer. Pp.292. ISBN 0-7167-1355-1. (W.H. Freeman: 1982.) $28.50, £11.95.

IT IS HARD to criticize a man who agrees with you. In *Contact with the Stars*, newly translated from the 1978 German publication, Reinhard Breuer presents a view of extraterrestrial life which is becoming something of a new orthodoxy in science: the view that the development of life and of technology is not nearly as straightforward as was thought during the salad days of the 1960s, and that humanity, far from being a junior member of a widespread "galactic club", may, in fact, be a unique feature of our galaxy.

Such a view has many sources, one of which is the pioneering work of Michael Hart on the evolution of planetary atmospheres. Hart showed that the various forces that shape atmospheric development — chemistry, vulcanism, stellar evolution and the effects of life itself — comprise a finely balanced system that would require very little in the way of perturbation to upset it. In the case of the Earth, for example, the atmosphere has been undergoing changes in composition over its four-billion-year history, a period when the brightness of the Sun was increasing by 25 per cent. Life is possible on the Earth only because these two changes took place in exactly the right sequence to cancel each other out. One misstep and the Earth would have experienced a runaway greenhouse effect like Venus or become a frozen ball like Mars or Titan. As I write this, watching my daughters playing in the surf at Cape Hatteras, it is hard to imagine that everything I see — the clouds, the people, the ocean itself — is the result of a happy set of chance occurrences that are unlikely to have been repeated elsewhere. Yet that is precisely what the past 20 years of research on the origins of life tells us.

Another strong argument against the existence of copious numbers of extraterrestrial civilizations is attributed (perhaps apocryphally) to Enrico Fermi. When first presented with the statement that the number of such civilizations in the galaxy could well surpass a million, he is supposed to have remarked "Where is everybody?". The point is that it does not take much imagination to envisage the emergence of humanity as a star-faring race. The idea that we have the technical ability to colonize the entire galaxy is not difficult to accept in the age of space exploration, and calculations tell us that a wave of colonization centred on the Earth would sweep through the galaxy in some 30 million years — a mere blink of the eye in the lifetime of the cosmos. If there really are a million other races out there, most of them will be older and more advanced than we are, so one can argue that the fact that they're not *here* is strong prima facie evidence that they're not *there*, either.

These two types of evidence — one from the study of the origin of life, the other from consideration of the human future in space — have convinced many members of the scientific community that the optimistic estimates of the abundance of extraterrestrial life bandied about in the 1960s and 1970s were simply wrong. As so often happens when new evidence arrives on the scene, old orthodoxies must give way to new. The "galactic club", conducive as it may be to good science fiction, is no exception to the rule.

Contact With the Stars must be understood, then, in the context of the general scientific counter-revolution on the subject of extraterrestrial civilizations. The new ideas have yet to percolate through to the general public, of course, but they are already well known to the experts. The book touches on all of the main topics related to the development of life — stellar evolution, genetic coding, space colonies, UFOs and so on. Some of the topics are treated very well. For example, I got a great deal out of Breuer's discussion of the debate on whether or not we have reached the end of the line in biological evolution. Unlike some who claim that a vastly superior human race will result from genetic engineering, Breuer argues that the genetic code is already carrying just about all the information it can, given the unavoidable copying errors which must occur in replication. This general attitude of informed scepticism is the greatest strength of the book.

On the debit side, the book reads more like a series of unconnected lectures than a single, cohesive document. The author often ventures into asides that range far from the topic under consideration. For example, after having repeatedly asserted his belief that we are alone in the galaxy, he launches into a lengthy and detailed discussion of strategies for communicating with the very extraterrestrials who aren't supposed to be listening. One can only wonder as to why so much effort has been spent devising complex pictographic codes if attempts to communicate are necessarily doomed to failure. ☐

Books for Christmas

THE next review supplement to be published in *Nature* is Christmas Books, which will appear in the issue of December 9th.

As well as articles on recent science books for children, and on bird books and space science/astronomy books, the supplement will include reviews of *Aha! Gotcha, Darwin for Beginners, More Random Walks in Science, The Cult of the Expert* and *A Geological Miscellany.*

Time as time out of sight and mind

P.W. Atkins

On Time: An Investigation into Scientific Knowledge and Human Experience. By Michael Shallis. Pp.208. ISBN 0-09-148950-4. (Burnett Books/Hutchinson: 1982.) £8.95.

THERE are three types of scientist. One type believes that the whole of human experience is open to scientific investigation and rationalization. Another type believes that there are aspects of the world that lie outside the scope of science. The third type doesn't care one way or the other, and simply gets on with the job. The author of *On Time* is a member of Class 2; I am a member of Class 1, and therein lies a profound disagreement.

Dr Shallis has addressed himself to one of the most elusive aspects of the world: the nature of time. He takes us through a sequence of attitudes to time, ranging from its measurement, through its role in physics (encompassing relativity, entropy and causality), and ends with a series of chapters dealing with what most hard-nosed scientists regard as outside their domain, and lying beyond credulity. All this he treats with an engaging earnestness that fully captures his intention of approaching his subject with "the scientific attitude . . . of a wide-eyed child".

I suspect that you will like this book if you believe that there are aspects of the world outside science; for all *aficionadós* of the paranormal warm to support from within the ranks of practising scientists. I suspect, also, that if you do not believe that science is incapable of dealing with these purported phenomena, such as by dismissing them as hoaxes or by explaining them in terms of established physics, then you will find this book a distressing mish-mash of credulity and passion. What you will not be able to complain about is, as the author so disingenuously reminds us, the impossibility of not going the whole hog on the paranormal once you have embarked on its foothills.

I was particularly struck by one phrase that occurs early on, where Dr Shallis remarks that, by extending conventional "instructional" science to encompass the unreproducible, occasional events that he thinks sometimes obtrude into the world too spasmodically to be captured by scientific method, he provides a description of reality which "will inevitably be richer than the former one". It seems to me that exactly the same remarks are made in favour of the use of hallucinogenic drugs; and with as much force. The heightened richness Dr Shallis asks us to accept (while acknowledging that it may inspire scorn) includes just about everything that may be regarded as symptomatic of crackpots: astrology, precognition, angels and gods (with, I think, fairies and bent teaspoons thrown in for good measure). Some idea of the style of argument is captured by the manner in which the book speaks of α-emission. Apparently, this process is "absolutely causeless" (p.119) except for the possibility that it may be "influenced by mind" (p.125) — particularly, it seems, the minds of young chicks.

I hope that enough has been said to represent without distortion the thrust of Dr Shallis's argument: be totally credulous, swallow the whole of the paranormal, give weight to the hallucinations of the wishful thinking and the downright potty, and disregard the successful continuing progress of modern science. If you accept that argument then you will indeed accompany the author as far as his conclusion, that time is intrinsically paradoxical and must for ever remain elusive. The rejection of that argument, which in the face of the evidence presented here doesn't seem to present much difficulty, keeps open the path to comprehension. ☐

P. W. Atkins is a Fellow of Lincoln College and Lecturer in Physical Chemistry at the University of Oxford. He is author of The Creation *(W.H. Freeman, 1981).*

Breaking the laws

Michael Berry

The Accidental Universe. By P.C.W. Davies. Pp.139. Hbk ISBN 0-521-24212-6; pbk ISBN 0-521-28692-1. (Cambridge University Press: 1982.) Hbk £10, $19.95; pbk £4.95, $9.95.

WHAT would the world be like if the force of gravity were a little stronger? If the proton were a little lighter? It is the purpose of Paul Davies's latest book to study questions such as these and, more generally, to explore the sensitivity of various features of the Universe to the values of the fundamental constants of nature. As groundwork the book begins with an account of the laws of physics and the scales on which they operate, from the shortest "Planck" lengths and times, through those characteristic of nuclear physics, up to cosmological ones.

The main body of the work is devoted to showing how these levels of structure are exquisitely interlocked, so that a change in one level can have astonishing repercussions elsewhere. For example, if the strength of the weak nuclear force (compared to gravity) were slightly different, this would greatly affect energy transport in stars, and probably prevent supernova explosions spewing forth the heavy elements which condense into planets and ultimately ourselves. If the strong nuclear force were a few per cent stronger or weaker there would probably be no stars at all. And if the primordial energy density had been minutely different, the Universe would either have re-contracted implosively long ago (and long before stars and planets could have formed) or exploded so violently as to inhibit condensation into galaxies. Related to this sensitivity are the celebrated "coincidences" involving large numbers; for example, the ratios of the age of the Universe to the time for light to cross a nucleus, and of the strength of gravity to the strength of electromagnetism, are both about 10^{40}.

By examining an impressive variety of such cases (basing his arguments largely on a review article by B.J. Carr and M.J. Rees — *Nature* **278**, 605; 1979), Davies concludes that the Universe is so "fine-tuned" to its present condition by the values of fundamental constants that even a very small alteration would produce a world vastly different from ours and almost certainly unable to support life physically constituted as we know it. This leads him into a discussion of the anthropic principle, which in its weak form asserts: "What we can expect to observe must be restricted by the conditions necessary for our presence as observers", and in its strong form asserts: "The Universe must be such as to admit the creation of observers within it at some stage".

This sudden emergence into cosmology of the idea that the physical structure of the Universe is very special and related to its cognizability is rather strange. It seems to be connected in a curious way with the current preoccupation in applied mathematics with the concepts of genericity and structural stability as especially emphasized by René Thom. Much effort is being expended to determine the nature of the generic (that is, typical, or non-special) solutions of the equations representing physical laws, in the belief that these, being stable against perturbation, can represent persistent structures (condensed matter or life, for example). But the equations themselves are highly non-generic; Maxwell's laws of electromagnetism, for example, are a very special set of linear relations which strongly constrain two vector fields, and any modification would lead to wrong "laws". In this picture of generic solutions of non-generic equations it is difficult to see how the fundamental constants fit in: are they "random initial conditions" or are their ratios determined by laws we do not yet know?

The consequences of physical laws have been explored much more extensively employing the actual ratios of fundamental constants than with hypothetical modified values. It might be that evolution towards structural complexity is virtually irresistible, would survive such modification and still lead to intelligence (albeit with a physical basis quite different from ours — Olaf Stapledon's novel *Star Maker* comes to mind, with intelligence developing via organized fluid motion in the wisps of galaxies and, later, inside stars). If this is correct — that is, if in the space of fundamental constants it could be shown to be generic for universes to have intelligence as an "attractor" of physical laws — the strong anthropic principle would follow as a marvellous consequence, and this aspect of the "coincidences" would lose its mystery.

Paul Davies does not devote much space to such speculations but quite properly concentrates on explaining the physics underlying them. He does this with the lucidity and authority we have come to expect from him. The book should be accessible to anyone with an undergraduate acquaintance with physics, and I warmly recommend it as an excellent introduction to this new and important idea. ☐

Michael Berry is a Professor in the H.H. Wills Physics Laboratory, University of Bristol.

Common ground in a changing climate

Hubert Lamb

The Earth's Climate: Past and Future. By M.I. Budyko. Pp.307. ISBN 0-12-139460-3. (Academic: 1982.) \$39.50, £26.20.

THIS important book by the Soviet Union's outstanding climatologist, Professor M.I. Budyko, is a landmark in the development of climatology as a branch of physical science. At the same time, because climate itself touches more or less every aspect of life on Earth, and because of the way the author draws on the varied works of his long and active career, the book ends by being a statement of Budyko's life philosophy and perhaps of the broadest view of the world as seen from the Soviet Union. As such, it is not only an important work (and one written with notable lucidity) but of wide interest.

Since about 1960 Budyko has been actively involved in concern over man's impact on the environment and with the possibility that the overall effect of the accelerating increase of carbon dioxide in the atmosphere might so disturb the balance of in- and out-going radiation as to lead to an unacceptable warming of the Earth. He was also among the first to discuss the feasibility of counter-measures, such as introducing an aerosol veil into the stratosphere to reduce the warming.

The Earth's climate is some 40°C warmer than would be expected at this distance from the Sun thanks to the extent to which out-radiation is intercepted by the carbon dioxide, water vapour and so on in the atmosphere. Among the most interesting features of Budyko's book is the way in which he traces the changes of climate through the geological past in terms of the carbon dioxide and water supplied by volcanic activity. Decline set in as the volcanism eased off and as vegetation appeared and increased, removing carbon dioxide and converting it to oxygen. This decline was accompanied by a lowering of temperature and the appearance of polar ice. Other shorter-term temperature drops have been associated with periods of specially active volcanism and frequent loading of the atmosphere with veils of dust and aerosol.

However, not all geologists agree that the record of carbon dioxide in the atmosphere fits so well with the known history of prevailing temperatures. Nor can the temperature history of the past century or more be explained by carbon dioxide alone. I am concerned that not only Budyko's book but prevailing opinion among leading meteorologists and climatologists may seriously over-emphasize the importance of carbon dioxide *vis-à-vis* other causes of climatic change. In this book it turns out that in 101 pages carbon dioxide is considered as a major cause of climatic changes, compared with 21 pages for volcanism, and 25 pages for the capacity of polar ice variations and other albedo variations to amplify the overall effect on world temperature. Possible variations of the solar constant get two pages, variations of cloudiness five pages, and continental drift/polar wandering and the Earth's orbital variations about four pages each. The last named variables are surely under-stressed.

The frequent forecasts nowadays, in this book and elsewhere, of a coming drastic change of climate due to man's production of carbon dioxide (and other effluents) are in general a good deal too confident. Despite its basis in the laws of physics, so well expounded in this book, climate is the product of a complex of influences that defies precise modelling. There is no clearly definable limit to the range or the rate of natural climatic variability, particularly the coolings associated with waves of volcanism and (perhaps) other causes. Once within the past 300 years, between 1690 and 1750, there was an oscillation which changed the ten-year average temperatures in England by nearly 2°C, probably the local expression of a global phenomenon. Carbon dioxide changes can be presumed to have played no part in this. The prevailing confidence in the carbon dioxide forecasts is based on their grounding in straightforward physics, but our experience of the difficulties of short-range meteorological forecasts is not entirely irrelevant to this problem.

That said, the possibility of a drastic

climatic warming due to the carbon dioxide has nonetheless to be taken seriously and Budyko has long been pressing upon scientists and politicians alike the urgency of the matter. On the one side, the increase of carbon dioxide could, if its effect were not counteracted by natural or anthropogenic influences, warm world climate by as much as 3°C within about 50 years — and possibly by 10–15°C in the highest latitudes, with disappearance of the polar ice. This and the corresponding changes in the rainfall pattern would be expected to shift the agricultural crop zones and the desert boundary northwards by a highly inconvenient number of degrees of latitude. This would also initiate the rapid melting of the land-based ice-sheets in Greenland and elsewhere, possibly including the great ice-sheet in Antarctica, with a consequent rise of ocean level that would overwhelm the Netherlands and drown large parts of the world's biggest cities. On the other side, forward calculation of the astronomical (Earth's orbital) variations points to a new ice age beginning within about 5,000 years (not the 10,000 to 15,000 years mentioned in the book on the basis of an outdated calculation).

Against this background Budyko sees the increase in carbon dioxide through burning fossil fuel as a benign effect if only it can be moderated to a slower rate of change to which we may be able to adapt. In his eyes man is restoring the atmosphere to its state before the growth of vegetation and is thereby prolonging the possibility of existence of human life and of a biological environment sufficient for our needs. Otherwise the continuing natural decline which set in before the Pliocene would, he suspects, doom the biosphere to extinction within one million years. There are interesting asides in his final chapter about the uniqueness of the Earth's biosphere and the improbability of life, let alone technologically proficient beings, elsewhere in the Universe. On another page, he develops a vision of the future made possible by our postponement of the run-down of carbon dioxide in the atmosphere: a future with a much denser human population and more varied life-forms and, presumably, accelerated through-put of the food chains. Not everyone, however, will see that as progress to a better world.

But in the end there is a noteworthy agreement between the conclusions reached on both sides of the cultural and philosophical divide about our situation in the world today, particularly as regards the threat that man's activities present to our planet. Budyko quotes a Soviet colleague, mentioning a well-known statement by Karl Marx, that

> culture leaves behind itself a desert if it develops spontaneously and is not directed deliberately . . . a developed society ruins nature and destroys the environment from which it derives all its resources.

In this we are no better than our primitive ancestors, whatever their thoughts about the world, who ran so many species of the animals they hunted to extinction. To avert the danger, mankind "must form [take charge of] nature on the global scale". This demand for a cultural dictatorship corresponds to the recognition in informed Western circles of our responsibility towards our successors on Earth and of the need for controls and restraints based on wise counsels and better knowledge. □

Philosophy in retreat

Stephen Hawking

Cosmology, Physics, and Philosophy. By Benjamin Gal-Or. Pp.522. ISBN 0-387-90581-2. (Springer-Verlag: 1982.) DM 69.

THE ancients considered the ultimate question of "Life, the Universe, and Everything" to be part of philosophy even though they were not sure that the answer was 42. For instance, Aristotle wrote a book on the structure of the heavens in which he put forward good reasons for believing that the Earth was spherical and even gave a figure for the circumference that was correct to within a factor of two. Other philosophers up to and including Kant also considered the structure of the physical Universe to be within the arena of philosophy.

In more recent times, however, philosophers have largely abandoned cosmological questions to physicists and have shrunk the scope of their enquiries to such an extent that many of them now hold that "the sole remaining task for philosophy is the critique of language". Although physicists have brought about great changes in our ideas about the Universe and in our concepts of space and time, they tend to shy away from questions that they regard as philosophical or metaphysical like "does time have a beginning" or "why is the Universe the way it is".

Benjamin Gal-Or, the author of *Cosmology, Physics, and Philosophy*, bemoans the gulf that has grown up between philosophy and cosmology and attempts to bridge it by informing philosophers about the modern theories of physics and by trying to interest physicists in philosophy. In the first of these endeavours he may have some success. The book contains a reasonable account of the hot big-bang theory. It is however overlaid with a lot of other ideas from the modern literature on theoretical physics which the author has included rather uncritically, even though they may not be relevant to the main contents or they may be ephemeral and not taken very seriously by others in the field. An example of this is a flow diagram in the introduction which is meant to show the relations between the main ideas in the book but which is more like a maze with about 40 or 50 boxes connected by arrows. I feel that non-physicists who want to find out about modern theories of the Universe might do better to read the clear and reasonably short book by Steven Weinberg entitled *The First Three Minutes*.

The book's attempt to inform physicists about philosophy is not very successful, at least as far as this physicist is concerned. I found it rather confused and verging on the mystical. One is frequently enjoined to cast aside prejudices and to embrace "gravitism" and "havayism", which is supposed to be the science of the whole, though it was never clear to me what one was supposed to do with them. I also found it rather irritating to have about a quarter of each page in italics for emphasis. Nevertheless, the task that Gal-Or has attempted is a very important one and this book will have to serve until someone writes a better one. □

In muddied waters

Michael Ruse

The Shaping of Man: Philosophical Aspects of Sociobiology. By Roger Trigg. Pp.186. Hbk ISBN 0-631-13023-3; pbk ISBN 0-631-13028-4. (Basil Blackwell: 1982.) Hbk £12.50; pbk £5.95. To be published in the USA next year by Schocken Books.

THE study of animal social behaviour from an evolutionary perspective dates from the publication of Darwin's *Origin*. But, for a number of reasons — not the least of which is its sheer difficulty — such study languished for a century; and this despite the valiant efforts of a number of workers, most notably and creditably the so-called "ethologists". However, in the past 10–15 years, this member of the family of evolutionary science has awoken, and now races ahead, both theoretically and empirically. Under the new rubric of "sociobiology", the biological basis of animal social behaviour is a rich hunting ground for the brightest and most ambitious of graduate students.

Yet, not everyone has welcomed sociobiology; at least, not everyone has welcomed sociobiology as applied to our own species, *Homo sapiens*. Expectedly, left-wing thinkers are wary of any attempt to relate human behaviour to genes, and they have been joined in their opposition by others. To my regret, members of my own discipline, philosophy, have added their voices to the chorus of dissent, happily "proving" that not only is human sociobiology pernicious and dangerous, but that it is also conceptually impossible! I speak of "regret", because although it is undoubtedly the case that some pretty daft things have been said by advocates of human sociobiology, it surely should be of some moment to us as philosophers that human beings are modified monkeys, rather than the miraculous recent creations of a Being determined to produce offspring in His own image.

The pendulum of opinion now appears to be swinging back, however, and Roger Trigg's new book is happy confirmation of this fact. He is far from an uncritical devotee of human sociobiology, but equally he is convinced that as philosophers — as inquirers into the ultimate nature of man — "we reject the findings of human biology at our peril" (p. xviii).

What is man? Trigg runs through a number of answers and this large survey is one of the irritating aspects of the book; it takes an interminable time before the author turns to his sub-title and to biology. For some one hundred pages we get a Cook's tour, as Trigg takes us rapidly through a selection of the many non-biological answers that have been given to his question. In fairness, the tour is not without value. I am reminded of Woody Allen's comment about how philosophy frustrated him, because he could never tell the difference between heuristics and hermaneutics. He should read Trigg's book, for he will find the solution to that problem, as well as to many others.

Specifically, Trigg introduces us to those such as B.F. Skinner and David Hume who would treat man as object. Some familiar, but nonetheless pertinent objections are raised, for instance the inability of those who regard man as an object to regard themselves as objects! Then Trigg looks at those who take the opposite tack, regarding man as subject. Included here are such thinkers as J-P. Sartre, R.G. Collingwood and H. Gadamer. The difficulties in this approach are noted, including that of ever escaping from the relativism which stems from the overall presuppositions. Next, Trigg looks at sociological approaches to man (his answer is that they are limited), and discusses whether man is a genuine species (yes, but this doesn't tell us as much as we might hope).

And so, finally, we get to the question promised by the book's title: "Is biology the key to the nature of man?". Trigg's answer is guarded. On the one hand, he agrees that biology — specifically human sociobiology — seems to have at least the potential to throw light on human behaviour and its causes; on the other, he warns of the limitations and confusions in the biological approach.

I confess that there were times through this part of his discussion when I felt that Trigg was being a little less than fair to sociobiology (or, at least, to its proponents). Sociobiologists are certainly aware of obvious traps. For instance, if one explains behaviour through (say) kin selection, then although causally one is thinking in terms of reproductive benefits to the individual, it does not follow that one can draw sweeping claims about all humans being "selfish" or some such thing. Talk of "selfish genes", for instance, is metaphorical, and does not commit sociobiologists to the thesis that every human being is a conscious self-interested schemer.

Yet at this point, Trigg accuses sociobiologists of "muddying the waters" for they juxtapose "altruism with an ordinary notion of advantage and self-interest" (p.117). Rather it is Trigg who is muddying waters, or at least who is accusing sociobiologists of being more naive than they really are. Surely he would not suggest that any attempt to give a causal analysis of human behaviour is doomed to failure? Nor even would he suggest that all causes must be related at once to our immediate conscious awareness. Suppose one says that an adult behaves well because of strict childhood discipline. This may or may not be true, but seems to makes sense if the adult does not usually consciously remember the childhood training. If this is so, why is it wrong in principle for sociobiologists to formulate explanations using factors which operate below (or outside) the level of consciousness? And why should they not use metaphors such as "selfish"? Every other scientist uses metaphors (force, work, energy, power, attraction, repulsion and so on).

Finally, Trigg raises the relationship between biology and morality. Again, his conclusion is cautious:

> The insights of sociobiology may give us further understanding of man's nature and give us material on which to base our claims. They cannot take away from us the capability of rational moral choice, based on our conception of the nature of man. The paradox is that any attempt through rational argument to treat man as merely another animal, no different from other animals, is itself self-refuting [p.162].

I'm not quite sure of the strength of this supposed paradox. Is it empirical, in that man simply seems different from other animals? Or is it necessary, in that the very attempt to explain ourselves proves that biology is limited in power? Either way, my own inclination is to agree with Trigg that there is more to morality than biology, in the sense that one certainly cannot deduce morality from biology. Our biological urges are not always "good" urges. Nevertheless, I would go further than Trigg — if indeed we are the product of evolution, then our moral sense presumably has some adaptive value, and hence biology can perhaps throw light on the content of our biology. Biology may not justify in some absolute way our sense of the worth of human being, but it can show why we have such a sense. And perhaps this is all the proof we can ever hope for.

Clearly I don't agree with some of Trigg's conclusions, any more than he would with mine. But that is the nature of philosophy (nor is such disagreement a sign of any inherent weakness in the subject). What counts is that although he is over-long in getting to his main theme, Trigg stimulates one to think on important matters. And that is no small praise. ☐

Michael Ruse is a Professor in the Departments of History and Philosophy at the University of Guelph. His book Darwinism Defended *was published earlier this year by Addison-Wesley.*

Good, bad & biology

Marian Dawkins

The Nature of the Beast: Are Animals Moral? By Stephen R.L. Clark. Pp.127. ISBN 0-19-219130-6. (Oxford University Press: 1982.) £7.95, $14.95.

STEPHEN Clark has made a tactical error. He is a philosopher writing about animal behaviour and attempting to explore the possible analogy between what animals do and human morality. But he unfortunately fails to conceal his contempt for biologists and many of their theories about animals. "The philosopher at a gathering of biologists", he remarks in the Introduction, "is the one in a state of permanent exasperation that these scientists do not understand their own concepts!". He dismisses various biological theories as "merely ridiculous" or "broken-backed and to point this out should be a job for any competent editor, let alone a philosopher".

Writing about a subject which is not your own is always hazardous; but to write in such a way that you raise the hackles of those working in the field before you have even got down to saying what you want to say is hardly the way to persuade biologists that a dose of philosophy would be a good thing. I say this because my own reaction to the book was strongly coloured by resentment at a number of implications, such as that all ethologists are right-wing ideologues who have to be taught a lesson on how to think straight. This resentment probably made me less tolerant of factual errors, more irritated by grammatical awkwardness and far less open to the contribution this book may make than I would have been had exactly the same ideas been put over in a different spirit. For the subject of the book — whether what human beings regard as "moral" has anything to do with what animals have been shaped by natural selection to do — is an important one. There has indeed been a lot of muddled thinking and perhaps facile generalizations from other species to our own. So having expressed my irritation, I will now try to concentrate on content rather than style.

Dr Clark is concerned with what he calls the "morals of Nature". Parent animals care for their children, do not always kill their rivals and apparently respect sexual taboos and figures of authority. There are at least superficial similarities between these examples and conduct which we would call moral if it were done by a human being. But would we be right to describe such behaviour as moral in a non-human species? Are the inhibitions that a wolf feels when it stops short of killing a rival anything like moral ones? And can we learn anything about human morality from studying animals?

To answer these questions, Dr Clark examines various aspects of animal behaviour, including parental behaviour, territory and dominance, drawing on considerable factual detail in the process. He then comes to the conclusions that other animals are not moral in the usual human sense of the word because they do not have the ability to see that they could be wrong. He describes animals as ethical because they "respond to aspects of a situation and to features of their kindred, that a good man would also respect". But he says they are not moral,

> for they do not, as far as we can see, have any occasion to moralise about themselves or to construct intellectual systems to accommodate their immediate responses.

So far Dr Clark's conclusions are easy enough to follow (apart from reservations about some animals which behave in ways which a good man might not respect), but they are neither very surprising nor very different from common sense. It is when he tackles the question of whether human beings should, in any way, adopt the "morals of Nature" that it becomes much more difficult to see what he means. He believes that "the ways of the beasts can set us good examples". Yet he has already argued that the "beasts" are not moral, so it is not clear why he thinks they may set us moral examples. He also believes that some of our moral habits, such as caring for relatives, are "bred into" us. And yet he firmly states that morality does not and cannot come from biology.

One is, in short, left more confused at the end of the book than at the beginning. His scathing criticisms of biologists might have been a great deal easier to stomach if he himself had been able to show that clarity of thought that he feels biologists so obviously lack. ☐

Separated learning and symbol making

Carolyn A. Ristau

The Unique Animal: The Origin, Nature and Consequences of Human Intelligence. By Don D. Davis. Pp.336. Hbk ISBN 0-907152-02-3; pbk ISBN 0-907152-01-5. (Prytaneum Press: 1981.) Hbk £12.95, $25; pbk £6.95, $12.95.

Don Davis has a provocatively simple hypothesis of the difference between the minds of man and beast. He proposes that man alone is capable of separated learning — of proposing a connection between two or more events separated in time. This entails more than remembering over a long period of time; connecting two seemingly distinct events is essential. As a consequence only human beings can create symbols or discover a relationship between two non-contiguous events, and can hypothesize or propose such connections. Man's hypotheses flower in his magic, religion and science. Man alone has placed a seed in the ground one day, seen a plant grow at that place days later and connected the two events.

But is this the domain only of human beings as Davis claims? Ethologists might note, for example, that certain termites grow fungi and that some ants capture, tend and "raise" aphids for milking, although no one has shown that an individual insect could "discover" the relationships involved. Again, whether man is the only symbol maker seems highly debatable. At least some apes seem to have learned symbols taught by man — as Davis agrees — and some apes' use of novel sign combinations may be indicative of an ability to create a symbol. To conclude that natural animal communication is not symbolic may merely reflect a limitation of our methods of study. For example, the honey bee's dance may be a symbolic achievement when it is used to indicate the location of food.

Equally relevant is the question of whether man is the only creature that in learning can tolerate gaps between environmental events of more than a few seconds. Davis dismisses the obvious counterexamples — taste aversion learning and events that are marked by an especially salient stimulus such as a loud noise — as extremely narrow exceptions. Yet whether animals, like human beings, can "mark" events or locations (an ability that shares characteristics with the process of naming) remains a matter for both philosophical discussion and experimentation. Scent-marking by animals and food-caching with later retrieval may represent rudimentary forms of marking.

To be sure Davis's concept of separated learning *is* powerful, particularly given the way that contiguity as a prerequisite for learning has dominated experimental psychology for decades. No clear examples of such learning by animals come to mind, in contrast with the ease with which Davis is able to apply the concept to pre-historical science, the discovery of fire, of death's inevitability, of smelting, pottery, writing and record-keeping, and the interrelations of magic, religion and science.

Davis's book is of intellectual interest to a broad audience both scientific and popular. There are gaps in his references, however, particularly of pertinent recent research, leading to some incorrect generalizations; and some of his interpretations of research are questionable. But his ideas are important and provocative. They clearly merit attention. ☐

Carolyn A. Ristau is a Research Associate at The Rockefeller University, New York.

The pitfalls of bookmaking *(continued from p.112)*

▶ space as an entry in a telephone book. The main thrust (as publishers like to say) is by direct mail which ideally means a leaflet, brochure or booklet landing on the mat of potential customers quickly and reliably. However postal and handling expenses have escalated in recent years and even publishers who specialize in this type of marketing have drawn in their horns somewhat. There can be months of delay before the information about a particular book, especially if it appeals to small groups in different disciplines, reaches all possible readers. Campbell is bound to be on the list which is mailed last.

In the first year of publication perhaps as many as 800 copies will have been sold even though no one seems to know about the book. A further 200 sales will appear on the statement for the following year and then probably no more than another 100 over the next three years. Campbell, a reflective character, may wonder whether this is *the* way to reach the 1,100 purchasers who alone seem to be interested. Where is the electronic revolution? Even publishers stop and wonder, as they see the latest list of overstocks to be "wasted" because they are unsaleable, and ponder whether the print runs should in future be set below 1,000.

Meanwhile, over lunch with Parsons an adviser to the firm suggests there is room for a nice, tightly edited volume on the topic of Campbell's original chapter. The field has grown. The ideal editor would be Campbell himself, and he is approached. Does he accept? ☐

Anthony Watkinson, formerly Editorial Director of Academic Press, London, is now at Oxford University Press.

The Koloula Igneous Complex, on the island of Guadalcanal, consists of a low-K calc-alkaline sequence of 26 different intrusive phases. The major intrusions are characterized by $K/Rb > 400$, $Rb/Sr < 0.06$, $\delta^{18}O$ *of 5.7 to 7.2 and uniform* $^{87}Sr/^{86}Sr$ *of 0.70372. This article presents the first data describing oxygen and strontium isotopic behaviour within a plutonic suite that formed by crystal fractionation.*

TECTONIC settings of plutonic rocks (constructive versus destructive margins) in the geological past are often difficult to evaluate because of lack of data from recent plutonic complexes of known tectonic affinities. Such complexes are not commonly found because the very young magmatic terrains must be uplifted and eroded rapidly to expose the plutonic equivalents of the more commonly studied volcanic rocks[1,2]. Older plutonic complexes (such as the Sierra Nevada batholith) do not provide verifiable constraints on tectonic settings and as such are difficult to use for comparisons. We present new data on an oceanic-arc, sub-volcanic plutonic complex that is found on Guadalcanal in the Solomon Islands. Data from this complex can be used as a reference point for the evaluation of the tectonic setting and mantle–crust affinities of older plutonic complexes.

Geological setting

The Solomon Islands form a double *en echelon* straight arc between New Guinea and the New Hebrides island arc (Fig. 1). At present, subduction is from the south-west, with the Australian Plate being consumed beneath the Pacific Plate; although there is evidence that before the late Miocene the situation was reversed, with the Pacific Plate being subducted from the north-east beneath the Australian Plate[3]. The Solomon Islands form an oceanic island arc, and Guadalcanal has been near the site of major plate boundaries since at least the Cretaceous. Basement rocks include Cretaceous tholeiitic lavas, and some schistose equivalents, a Palaeocene gabbro, Oligocene–Miocene basaltic andesites (for example, Suta Volcanics) and their plutonic equivalents (Poha Diorite), and Miocene greywackes derived from basic volcanites[4]. The thickness of the basic crust in Guadalcanal is probably between 14 and 20 km (ref. 5).

The Koloula Igneous Complex (Fig. 2) is situated close to the south coast of Guadalcanal, some 50 km from the axis of the South Solomon Trench, which is the topographic expression of a steeply-dipping subduction zone, to which the Pliocene to Recent volcanic centres of Guadalcanal are genetically related[6]. The Koloula Igneous Complex (age: 4.5–1.5 Myr) is considered to have a similar origin, and is exposed solely because of rapid uplift (at least 2 km since the early Pleistocene) and immense erosion caused by seismically-triggered landslides and heavy rainfall, which at present is variable between 7.5 and 15 m yr^{-1}. Despite dense jungle, present exposure is excellent owing to a dense network of deeply-incised streams. Previous studies have dealt with the petrography and porphyry copper mineralization[7], K–Ar geochronology[8], fluid inclusions[9], and mineralogy[10,11] of the Koloula Igneous Complex.

The Koloula Igneous Complex has intruded the Suta Volcanics of late Oligocene–Miocene age, and consists of a low-K calc-alkaline sequence of 26 different intrusive phases that has been divided into two major magmatic episodes[7]. Cycle 1 intrusions ($\geqslant$4.5 Myr) are, in order of intrusion: Chakachaka Gabbro (including an olivine pyroxenite cumulate), diorite, Vasuata Quartz Diorite, granodiorite and aplite dykes. The latter two silicic units are volumetrically insignificant whereas the gabbro and the quartz diorite are the largest two intrusions, and together comprise about 80% by area of the complex that is exposed at the present time. The gabbro is composed of plagioclase, augite, hornblende, hypersthene, magnetite and commonly 1–2% quartz; olivine is almost unknown. The quartz diorite contains plagioclase, hornblende, quartz, magnetite, trace clinopyroxene, and typically, at least traces of a graphic quartz–alkali feldspar intergrowth.

Cycle 2 intrusions (2.4–1.5 Myr) are divided into the Inamumu Zoned Pluton (IZP) (Fig. 2) and several satellite intrusions. The latter, and six generations of andesitic and doleritic dykes, are not part of the present study. The IZP is composed of six concentrically-disposed quartz diorite and tonalite units, aplite dykes, the Chikora Tonalite Porphyry, and trondhjemite dykes (listed in order of intrusion in Table 1). Quartz diorites and tonalites of the IZP contain plagioclase, hornblende, quartz, biotite and magnetite, and except for tonalites 2 and 3, are typically devoid of K-feldspar.

Major- and trace-element data

The variations of major- and trace-element contents of whole rocks versus silica describe smooth and slightly curved trends over the interval 45–76% SiO_2 and are considered to be due to crystal fractionation[12] (Fig. 3). These trends are caused initially by fractionation of amphibole and then by biotite, an observation similar to that noted by Taubeneck[13] for other tonalitic intrusions. P_2O_5 content exhibits a smooth convex-upward shaped trend, typical in magmatic suites formed by crystal fractionation of apatite[14]. The gabbroic rocks are generally strongly leucocratic as they are the residual fraction after the separation of the olivine pyroxenite unit. Their analyses display a much wider compositional scatter than those of the more siliceous rock types and this behaviour is probably related to variable amounts of pyroxene and olivine segregations in some gabbro samples.

With the exception of the late-stage aplite dykes present in both magmatic cycles, there is a compositional overlap of rocks from cycles 1 and 2 between 53 and 64% SiO_2 (based on 110 whole-rock analyses[12]). The major rock-types are characterized by low abundances of K (250–12, 750 p.p.m.), Rb (1–46 p.p.m.), and Ba (207–493 p.p.m.); high Sr (360–700 p.p.m.), moderately high K/Rb and K/Ba ratios and low Rb/Sr ratios. K/Rb and K/Ba ratios are lower for cycle 2 than for cycle 1. Some representative analyses are given in Table 1 and shown in Fig. 4.

Strontium and oxygen isotope data

Rocks and minerals from plutons belonging to both cycles 1 and 2 have been analysed for oxygen and strontium isotopic compositions (Table 1). The alteration associated with fluid circulation peripheral to known prophyry copper mineralization in the Chikora Tonalite Porphyry[6] has clearly affected oxygen and hydrogen isotopic compositions in altered rocks. For example, sample A.276, a sericite + calcite + chlorite + pyrite filled fracture has low $\delta^{18}O = 3.6$ and high $\delta D = -48$ which are commonly measured values in rocks affected by hydrothermal fluids. Isotopic evidence of hydrothermal alteration can also be seen in some samples (A.628, A.838, A.41) with less obvious petrographic evidence of alteration (see ref. 15). Unlike $\delta^{18}O$ values, $^{87}Sr/^{86}Sr$ ratios from altered samples are the same as values of unaltered rocks or are only slightly higher (0.7037–0.7038). If the alteration fluid were seawater, as has been previously inferred[7] and as suggested by $^{87}Sr/^{86}Sr$ ratios of the alteration minerals (laumontite and calcite), then the small shift in $^{87}Sr/^{86}Sr$ ratios is a reflection of low water/rock (W/R) ratios and the high strontium contents of the rocks (500–600 p.p.m.) relative to that of seawater (8 p.p.m.)[16]. Strontium and oxygen isotope compositions may be used together to determine W/R ratios and temperatures of water–rock equilibration[17]. For closed-system exchange, the strontium W/R (by weight) between seawater and rock, is given by:

$$W/R = \frac{^{87}Sr/^{86}Sr^{f}(\text{rock}) - {}^{87}Sr/^{86}Sr^{i}(\text{rock})}{^{87}Sr/^{86}Sr^{i}(H_2O) - {}^{87}Sr/^{86}Sr^{f}(\text{rock})} \times \frac{C^{i}(\text{rock})}{C^{i}(H_2O)}$$

where i = initial, f = final, C^i(rock) = concentration of strontium in rocks and $C^i(H_2O)$ = concentration of strontium in seawater. W/R ratios of 4 are calculated for completely altered rocks using data from calcite and laumontite veins where $^{87}Sr/^{86}Sr^f = 0.7040$ and the parameters $^{87}Sr/^{86}Sr^i(\text{rock}) = 0.7037$, $^{87}Sr/^{86}Sr^i(H_2O) = 0.709$, $C^i(H_2O) = 8$ and C^i (rock) = 550. The strontium contents of altered rocks and minerals (200–400 p.p.m.) are lower than those of unaltered rocks (500–600 p.p.m.) and suggest loss of strontium to the alteration fluid and that the system was not entirely closed. The assumption of closed system behaviour maximizes the calculated W/R ratio. At such low W/R ratios and high concentrations of strontium in the altered rocks, the shifts in $^{87}Sr/^{86}Sr$ composition associated with alteration are at the limits of our detection and without the oxygen-isotope data would probably go undetected. As such, use of alteration-related minerals (laumontite, calcite) provides evidence of strontium isotopic exchange that is well within analytical resolution. Using the W/R ratio obtained

above and the equation for closed-system oxygen isotope exchange of seawater and rock (by weight)[15]:

$$W/R = \frac{\delta^f(\text{rock}) - \delta^i(\text{rock})}{\delta^i(H_2O) - (\delta^f(\text{rock}) - \Delta)} \times \frac{C^i(\text{rock})}{C^i(H_2O)}$$

we can obtain values for Δ. For the alteration of the Charilava Quartz Diorite with seawater we obtain a value of $\Delta = 3.4$. Using the feldspar-H_2O geothermometer[18] ($\Delta = 2.68 (10^6/T^2) - 3.53$) we calculate a temperature of 350 °C for water–rock equilibration. This agrees well with the fluid inclusion filling temperature of 350 °C obtained on rocks from the same B4 alteration zone[9].

Using petrographic criteria and oxygen isotope compositions to eliminate altered samples, the unaltered rocks from cycle 1 have $\delta^{18}O$ values that range from 5.4 for a gabbro to 7.2 for an aplite dyke whereas $\delta^{18}O$ values from the IZP (cycle 2) range from 5.7 (quartz diorite) to 7.2 (trondjhemite dyke). The observed variations in $\delta^{18}O$ values (5.4–7.2) and SiO_2 contents (46–77%) fall along a well defined line with a slope of 0.06‰/% SiO_2 (Fig. 5). For these samples, $^{87}Sr/^{86}Sr$ ratios range from 0.70368 to 0.70378 ($\bar{x} = 0.70372 \pm 8$ at 2σ) for the entire range of SiO_2 and are identical within experimental errors.

The lack of variation in strontium isotopic ratios and the correlation of $\delta^{18}O$ with degree of differentiation (given by %

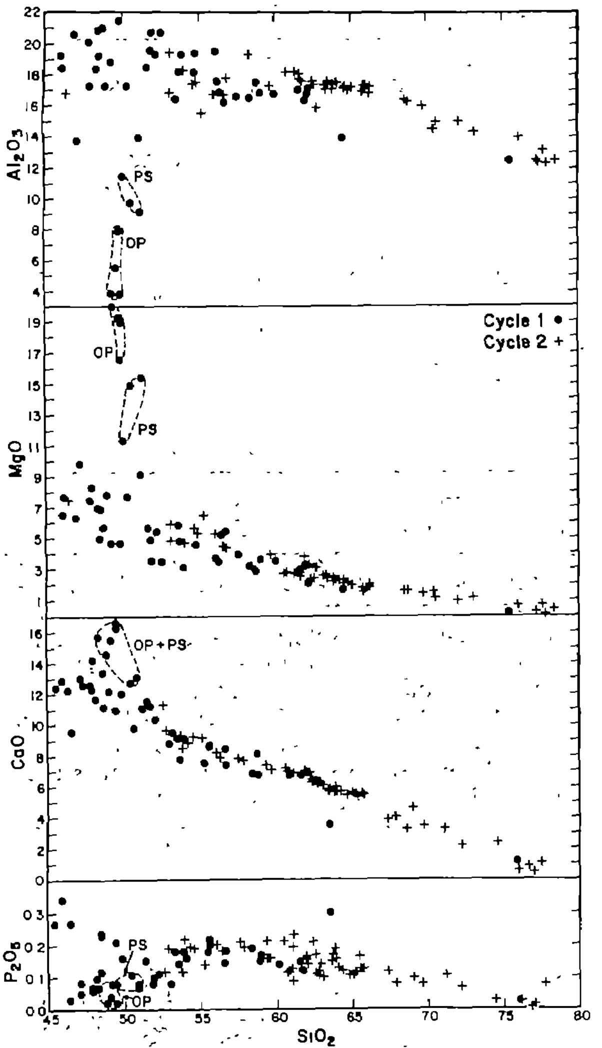

Fig. 3 Harker variation diagrams for selected major elements for samples from the Koloula Igneous Complex. OP, olivine pyroxenite; PS, pyroxenite segregation. Five samples of unusually mafic-rich gabbro provide a trend of high P_2O_5 contents between $SiO_2 = 45\%$ and 50%.

SiO_2) is indicative of temperature-dependent fractionation of oxygen isotopes. The magnitude of oxygen isotope fractionation between cumulus and liquid phases is dependent on the temperature of crystallization and the mineralogy of the cumulate hases in equilibrium with the liquid. As such, the slope of the correlation line on the SiO_2 versus $\delta^{18}O$ diagram for igneous rocks that have formed by simple crystal fractionation, will not be the same for all plutonic and volcanic complexes. However, for all igneous suites that have originated in the mantle, the correlation line should pass through a common field. In a suite of tholeiitic lavas from the Hachijo-jima volcano in the Izu-Mariana arc, Matsuhisa[19] found a $\delta^{18}O$ variation from 5.7 to 6.7‰ concomitant with a variation in SiO_2 of 47–73% (0.04‰/% SiO_2).

Comparisons with other epizonal plutons

Although well documented studies of subvolcanic magma chambers are rare, we have selected five examples that are probably related to arc magmatism (Table 2). Two of the areas are considered oceanic, two are continental and one, transitional from oceanic to continental. The oceanic plutonic complexes from Tanzawa, Japan and Viti Levu, Fiji are similar to the Koloula complex, in rock type (gabbro-tonalite) and geochemical data (Fig. 4). The Tanzawa complex is composed primarily of gabbro-tonalite plutons of Miocene age and has been interpreted as a low-K, island-arc plutonic complex[20,21]. The strontium isotope data from Tanzawa appear to be slightly anomalous in that the tonalites have an average $^{87}Sr/^{86}Sr$ ratio of 0.7036 whereas the gabbros give values of 0.70345. Although data are available from Viti Levu, it is obvious that significant alteration (10–20 modal % of alteration minerals) has caused considerable scatter[22]. Other geochemical characteristics (K, Rb, Sr contents) of the igneous complexes from both Tanzawa and Viti Levu are consistent with their having been derived from oceanic mantle with no crustal component. Measured K/Rb (>400) and Rb/Sr (<0.06) ratios are similar to volcanic rocks from other oceanic island arcs (for example, Tonga[23]). The Captains Bay pluton, Unalaska Island, Alaska[24] is zoned inward from gabbro to monzodiorite. Even though the $^{87}Sr/^{86}Sr$ ratios are similar to Koloula (0.70377), the low K/Rb (333–368) and the high Rb/Sr (0.08) for the quartz diorite are different. Based on conclusions of Perfit *et al.*[24] we have included the data under our oceanic plutonic complexes, but it is likely that Unalaska Island may straddle the continental–oceanic environments[25].

The continental-margin plutonic complexes related to subduction from both Chile[26] and western USA (Cloudy Pass[27] and Tatoosh[28,29]) are mostly tonalitic in composition and show consistently high K (>13,000 p.p.m.) and Rb (>42 p.p.m.) contents, high Rb/Sr (>0.08), and low K/Rb (<333). Lines with a Rb/Sr value of 0.06 and K/Rb ratio of 400 can be drawn in Fig. 4 that effectively separate oceanic and continental terrains. The limited strontium isotopic data (>0.7040) suggests a crustal component in the evolution of these plutons.

Except for Captains Bay, there is a notable lack of stable-isotope data for the examples cited so that we have little indication of the degree of alteration and its effects on other geochemical parameters. The large variation of $\delta^{18}O$ values from Captains Bay[24], of −4.1 to +5.7 is reflective of variations in $^{87}Sr/^{86}Sr$ ratios of 0.70328–0.70377 which can be caused by hydrothermal alteration.

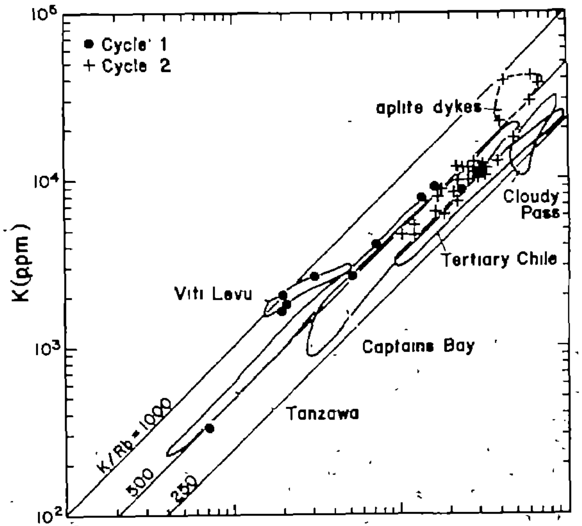

Fig. 4 K–Sr–Rb diagram for the Koloula Igneous Complex. Also shown are fields of gabbro to tonalite rocks from Tanzawa[21], Viti Levu[22], Captains Bay[23], Tertiary tonalites from Chile[26] and Cloudy Pass[29].

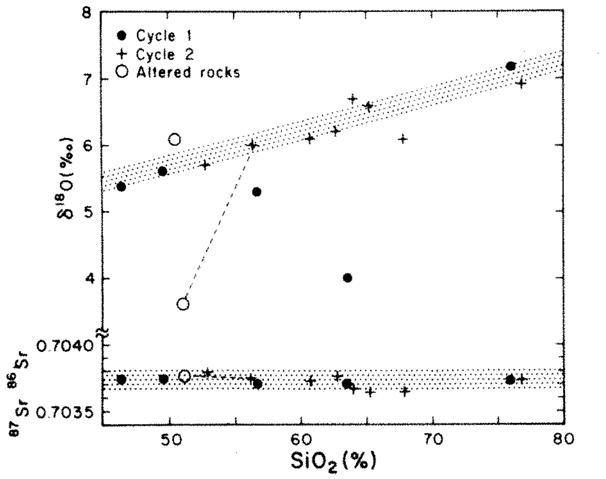

Fig. 5 Variation in whole-rock $\delta^{18}O$ values and initial $^{87}Sr/^{86}Sr$ ratios with % SiO_2 for samples from the Koloula Igneous Complex. Petrographic observations were used to characterize alteration. Tielines join altered and unaltered samples from the same intrusive phase.

Interpretation

The Koloula Igneous Complex is composed of 26 intrusive phases that range from gabbro to aplite. The youthfulness of the complex, its excellent exposure and our knowledge of its tectonic origins make the Koloula study unique in the geological literature. The geochemical variations seen within the two cycles of igneous intrusion are considered to be due to crystal fractionation. Within each cycle K/Rb and K/Ba ratios are similar and suggest that the members of each cycle are comagmatic. The difference in K/Rb and K/Ba ratios between cycles, with no difference in $^{87}Sr/^{86}Sr$ ratios and $\delta^{18}O$ values suggests a similar source for the magmas but different degrees of partial melting.

The large range in composition and relatively low and constant $^{87}Sr/^{86}Sr$ ratios observed in these rocks also makes it possible to model variations in oxygen isotope composition as related to crystal fractionation. Although such variations have been noted in volcanic rocks from Hachijo-Jima in the Izu-Mariana group[21], our data are the first to demonstrate these isotopic systematics in plutonic rocks resulting purely from crystal fractionation of a mantle-derived magma in a closed system. From our data which display relatively low $\delta^{18}O$ at high SiO_2 contents it becomes increasingly evident that examples of the more potassic suite, gabbro → granodiorite → granite are not a result of closed-system differentiation in either small (for example Ploumanac'h[30]) or large plutonic bodies (for example, Peninsular Ranges[31]). The evolution of these granites involves magma contamination by continental crust or partial melting of mixed mantle/continental source regions. Volcanic rocks from the Banda Arc also exhibit a correlation of $^{86}Sr/^{86}Sr$ with $\delta^{18}O$ that has been interpreted as being the result of contamination by crustal material or by subducted sediments[32].

From the comparisons with the limited data available from other young island-arc plutonic complexes, it appears that in unaltered complexes distinctions that are based on trace-element chemistries and isotopic ratios may be made between oceanic and continental environments.

Before this can be applied rigorously to plutonic complexes of uncertain tectonic environment, we need many more detailed studies of young complexes in known tectonic terrains. When this data base is established it may be then applied to older orogens where plutonic rocks are commonly the only remnants of volcanic activity.

Strontium isotopic analyses were performed at Virginia Polytechnic and State University's Geochemistry Laboratory which is supported by NSF grant EAR 7926340 to A.K.S.

The oncogene of the human EJ bladder carcinoma cell lines arose via alteration of a cellular proto-oncogene. Experiments are presented that localize the genetic lesion that led to activation of the oncogene. The lesion has no affect on levels of expression of the oncogene. Instead, it affects the structure of the oncogene-encoded protein.

0028-0836/82/450143—04$01.00

A LARGE body of work on chemical carcinogenesis has demonstrated that the carcinogenic potency of a compound is correlated with its mutagenic powers[1-4]; this suggests that DNA is the ultimate target of carcinogenic activation. Accordingly, we and others initiated a series of experiments designed to identify and study DNA segments in tumour cells whose alteration is critically important for oncogenic conversion[5-9].

An initial approach to this problem involved the transfer of tumour cell DNA into non-transformed NIH 3T3 mouse fibroblasts. Such experiments indicated that the phenotype of cellular transformation could be passed from cell to cell in this manner. Thus, the tumour DNA was able to induce foci of transformed cells in a recipient NIH 3T3 monolayer culture while DNA of normal, untransformed donor cells failed to do so[5-9]. These results demonstrated the existence of oncogenic factors which were present in tumour cell DNA and apparently absent from the DNA of normal cells.

That specific donor DNA sequences were involved in these phenomena was first indicated by studies examining the sensitivity or resistance of the biological activity of the DNA to treatment by various site-specific endonucleases[10,11], and was later directly demonstrated by molecular isolation of discrete transforming genes from human bladder carcinoma cell lines[12-14]. Use of clones of the bladder oncogene as sequence probes showed that the oncogene derived from a sequence of similar structure present in the normal human genome[12-14]. It appeared, therefore, that the bladder oncogene had arisen by the mutation of a normal cellular gene during the process of carcinogenesis. The present report addresses the nature of the alterations that activated the oncogene of the EJ human bladder carcinoma cell line.

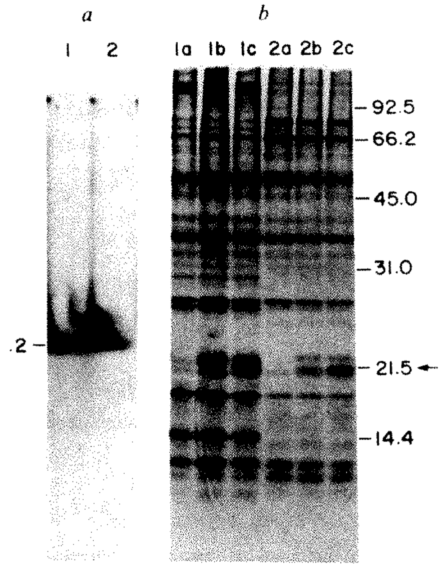

Fig. 1 Comparison of expression of the c-Ha-*ras* gene in normal human bladder epithelial cells with that in the EJ transformed bladder cell line. The normal bladder epithelial cells, strain HB1-5, were secondary and tertiary passage cultures derived from explants of a 5-month fetal human bladder. The cells were cultured as described[23]. *a*, The relative levels of c-Ha-*ras* specific RNA in the two cell types: lane 1, RNA from EJ cells; lane 2, RNA from Hbl-5 cells. Total polyadenylated RNA was prepared by the technique of Varmus *et al.*[40]; 4 μg of RNA was then fractionated by electrophoresis through formaldehyde-containing 2% agarose gels and transferred to nitrocellulose (B. Seed & D. Goldberg, manuscript in preparation). A *ras*-specific probe was prepared by cutting pEJ with *Bam*HI, fractionating the resultant fragments through a 1% agarose gel and extracting the 6.6-kb insert with NaI and glass beads. The nick-translated fragment (6.6×10^7 c.p.m. μg^{-1}) was annealed to the immobilized RNA[41,42]. Bands hybridizing to the probe were visualized by autoradiography. Molecular weights were determined by comparison with markers obtained from *in vitro* run-off transcription of the adenovirus late promoter[43]. *b*, A comparison of p21 proteins immunoprecipitated from cell lysates of EJ cell clones (lanes 1, a–c) and HB1-5 cells (lanes 2, a–c). Cultures were labelled with ^{35}S-methionine for 12 h. Lysates were then prepared and immunoprecipitated with non-immune serum (lanes 1a and 2a), a monoclonal antiserum (Y13-238) which precipitates the p21 encoded by Ha-MuSV but not the p21 encoded by Ki-MuSV (lanes 1b and 2b) or a monoclonal antiserum (Y13-259) which detects both the Ha-MuSV and the Ki-MuSV p21s (lanes 1c and 2c)[25,32]. 20×10^6 c.p.m. of lysate per sample were resolved by electrophoresis through a 12.5% SDS-polyacrylamide gel.

Comparison of this EJ bladder oncogene with the related cellular sequence (the proto-oncogene) was aided greatly by the subsequent discovery that this oncogene was homologous to the transforming gene of the rat-derived Harvey murine sarcoma virus[15-17]. This rat sarcoma virus gene, termed v-Ha-*ras*, had been acquired from the rat genome during the process of formation of the chimaeric viral genome[18,19]. Both the rat and human cellular homologues of v-Ha-*ras* have been isolated in the course of studies of this gene[20,21]. The human cellular homologue of the v-Ha-*ras* was found to correspond precisely to the normal antecedent of the EJ bladder oncogene[16].

From examination of the data in these cited reports, it was possible to make preliminary comparisons between the EJ oncogene[13] and its normal cellular counterpart (termed c-Ha-*ras*)[22]. For example, a molecular clone of the normal cellular gene did not induce foci when applied to NIH 3T3 monolayers, while a clone of the bladder oncogene exhibited a biological activity of $\sim5\times10^4$ focus-forming units per μg of transfected DNA[13,21]. This stark difference in function did not correlate with any apparent structural differences between the two clones. Rough restriction endonuclease site mapping of the EJ oncogene clone and the uncloned related human proto-oncogene indicated that the two were basically indistinguishable over the 6.6 kilobase (kb) of sequence which contained the transforming activity of the EJ oncogene[13]. Finer mapping was later made possible by the direct comparison of molecular clones of the two genes. We again found no differences using a series of different endonucleases, with the exception of a single difference 3′ (downstream) of the coding regions of the genes (data not shown). This latter difference was interpreted to represent a functionally silent polymorphism of the gene present in the human gene pool. Such polymorphisms of this gene have been documented independently by others[12].

These results presented an apparent paradox, since a drastic functional difference was exhibited by two structurally similar genes. We assumed that a minor alteration was responsible for the functional difference, and that this alteration could affect function in one of two ways: the alteration could involve a change in sequences regulating the expression of the gene; alternatively, the transformed phenotype could be due to changes in the protein-encoding portion of the gene. The first hypothesis would argue for up-regulation of transcription or translation of the gene, yielding high levels of an otherwise normal protein product, while the second model would suggest synthesis of an altered protein. Both types of alteration could also act in concert to create the observed difference in function.

Analysis of oncogene activity in normal and transformed bladder cells

If the significant difference between the oncogene and proto-oncogene were one of regulation, one would expect to see differences in levels of RNAs and proteins specified by these genes. To address this question, we first examined the EJ bladder carcinoma cells and their counterpart normal cells. Normal bladder epithelial cells were cultured from a specimen of normal human bladder as described[23], and were found to synthesize keratins, require a fibroblast feeder layer support, and to possess a limited lifespan in culture, as would be expected for normal epithelial cells (T. O'Connell and J. G. Rheinwald, personal communication). The cultures were free of human stromal fibroblasts, and were purified free of feeder cells before nucleic acid extraction. These cultured cells therefore provided a source of genetic material and RNA transcripts that were the normal counterparts of the bladder carcinoma genes and transcripts.

Total cellular RNA was prepared from both normal and transformed bladder cells. Transcripts were analysed by running the RNA on a formaldehyde gel, transferring it to a nitrocel-

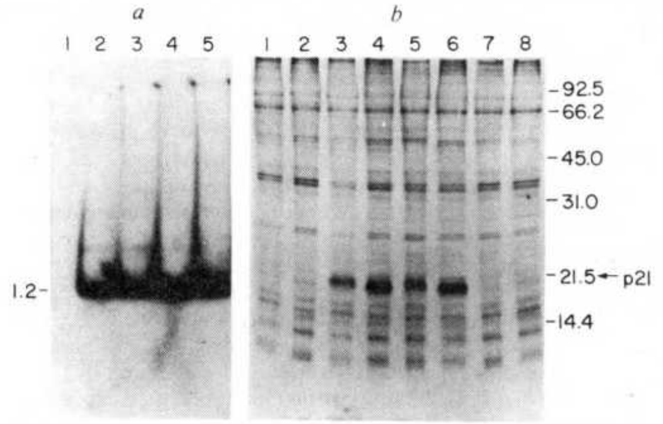

Fig. 2 Analysis of cells transfected with molecular clones of the EJ transforming gene (pEJ) or its normal cellular homologue (pEC). Transfections were carried out as previously described[44,45] using 75 μg NIH 3T3 carrier DNA, 500 ng pEJ or pEC DNA, and 50 ng pEcogpt DNA per 2×10^6 cells. Colonies resistant to mycophenolic acid were selected[26]. *a*, Analysis of total polyadenylated RNA from the four transfected cell lines. RNAs were isolated and analysed as described in Fig. 1. Lane 1, RNA from NIH 3T3 cells; lane 2, EJ/Gpt-2 cells; lane 3, EJ/Gpt-3 cells; lane 4, EC/Gpt-1 cells; lane 5, EC/Gpt-5 cells. *b*, A comparison of p21 proteins immunoprecipitated from cell lysates of the four lines transfected with pEJ or pEC. Cell lysates were prepared, immunoprecipitated and analysed as described in Fig. 1 legend. Immunoprecipitations were performed with non-immune serum (lanes 1, 2, 7, 8) or the monoclonal antiserum (Y13-238) which precipitates the Ha-MuSV p21 (lanes 3–6). Cell lysates were prepared from EJ/Gpt-2 (lanes 1, 3); EC/Gpt-1 (lanes 2, 4); EJ/Gpt-3 (lanes 5, 7) and EC/Gpt-5 (lanes 6, 8).

lulose filter, and probing the filter with nick-translated EJ oncogene clone. Figure 1*a* shows that similar levels of RNA were detected in the two cultures. The transcripts were of a size (1.2 kb) previously associated with the c-*ras* genes of other cell types[24].

The only known products of the *ras* genes are proteins of molecular weight ~21,000, referred to as p21. Monoclonal antisera against the v-Ha-*ras* p21 protein[25] were used to precipitate metabolically labelled protein lysates from both EJ and normal bladder cells. Control experiments ensured that the amounts of antibody used in this and subsequent experiments were in excess of that required to immunoprecipitate the antigen present. The data shown in Fig. 1*b* indicate that at least two bands of radiolabelled protein were specifically precipitated by the anti-p21 sera from normal bladder cells. Detailed examination of the protein pattern of the bladder carcinoma seen in this and other gels reveals a more complex array of bands. On close inspection we believe that four bands in total can be discerned. Data to be presented below clarify the origin of the novel p21 bands seen in the EJ tumour cells. After comparing the intensities of the p21 bands with those of non-specifically precipitated background bands, it became apparent that the total amount of p21 proteins of the normal and the tumour cells differed less than threefold.

It thus seems that increased levels of transcription are not responsible for the novel activity exhibited by the EJ oncogene. This conclusion rests in part on the fact that in the hybridization conditions used here, the oncogene probe reacts exclusively with transcripts of the human c-Ha-*ras*-1 gene. Interpretation of the protein data is less clear. It is apparent that both cells have comparable levels of proteins that are reactive with the Harvey-specific serum, and that these proteins can be collectively termed 'p21'. The nature of these proteins can only be addressed by other studies, presented in part below.

Analysis of gene activity in cells transfected with cloned DNAs

It remained possible that the bladder epithelial cells were not, as we believed, representatives of the normal precursors of the bladder carcinoma cells. Such a possibility might cloud interpretation, as a *ras* gene could be expressed at a high level in one cell type without inducing transformation, and only achieve this phenotype when inappropriately expressed in a second cell type. We therefore wished to measure the levels of transcription and translation of the two genes in the same cellular background.

We therefore introduced molecular clones of both genes into NIH 3T3 cells. Colonies acquiring the EJ oncogene could be readily identified by their transformed morphology. However, cells acquiring clones of the normal allele were not identifiable by any obvious change in behaviour. Because of this, we co-transfected a clone of the dominant selectable *Ecogpt* gene[26] into NIH 3T3 cells together with a 10-fold excess of either the cloned EJ oncogene (pEJ) or the cloned proto-oncogene (pEC). In each case, colonies were selected for resistance to mycophenolic acid imparted by acquired *Ecogpt* genes[26]. This strategy was used since the introduction of a non-selected DNA segment can be ensured by co-transfection with a selectable gene[27]. In the present case, 75% of the mycophenolic acid-resistant colonies deriving from co-transfection of *Ecogpt* and pEJ were seen to be morphologically transformed; as expected, none of the colonies emerging after co-transfection with pEC was transformed.

The cellular DNA of both classes of colonies was analysed for the presence of pEC or pEJ sequences. DNA was cleaved with the restriction enzyme *Bam*HI, which would be expected to liberate a 6.6-kb fragment from each intact copy of the cloned oncogene or proto-oncogene. The normal mouse homologue of the *ras* gene hybridizes only weakly to the pEJ probe[16], and so its presence does not obscure the analysis. To ensure that transfected pBR322 sequences would not interfere with interpretation of the data, *ras*-specific sequences were prepared from pEJ and used as probe; 75% of non-transformed colonies transfected with the proto-oncogene and all of the transformed, oncogene-transfected colonies showed the presence of pEJ-homologous sequences migrating at 6.6 kb (data not shown).

We selected for further analysis two cell lines containing intact copies of the oncogene and two lines containing an approximately equal number of intact copies of the proto-oncogene. Photographs of these cell lines are shown in Fig. 3; 4×10^6 cells of each of these lines were injected into 6-week-old NSF mice. Each of the pEJ transfected lines elicited tumours in 5/5 mice, while none of the mice injected in parallel with pEC transfectants developed tumours.

Total cellular RNA was prepared from all four transfected cell lines. The RNA preparations were then run on a formaldehyde gel, transferred to nitrocellulose filters, and probed with the *ras*-specific DNA. As shown in Fig. 2*a*, the level of *ras*-specific RNA in cells containing the oncogene was comparable with those carrying the transfected proto-oncogene. We also examined the levels of p21 in these cell lines. Figure 2*b* shows that monoclonal antiserum against p21 precipitates similar amounts of p21 protein in pEC and pEJ transfected cells.

These data do not address the question of whether the two cloned genes are transcribed at the same rates in these cells, as it remains formally possible that few of the acquired copies of the pEJ are active in these particular pEJ-transfected cells, while all copies of the transfected pEC gene in the other cells might be active. In such a case, the comparable levels of protein and RNA observed would not accurately reflect the instrinsic transcriptional activities of the two genes.

However, one point emerges with clarity from these experiments: a certain level of EJ-specified p21 induces transformation, while a comparable if not higher level of the proto-oncogene-specified p21 has no effect on cellular phenotype. Since the p21 proteins are the only apparent gene products encoded by these genes, we conclude that the difference in function between the EJ oncogene and the proto-oncogene must derive from structural alterations in the p21 protein. Conversely, regulatory alterations do not seem critical to the transforming activity of the oncogene.

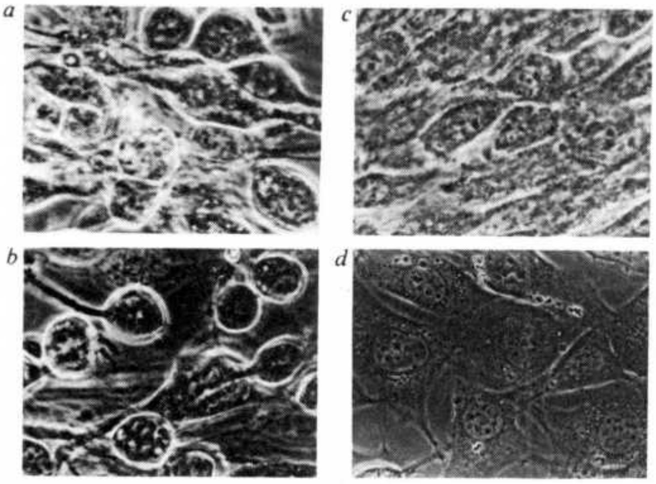

Fig. 3 Photographs of cell lines transfected with pEJ or pEC through a phase contrast microscope (×300). Cell lines were derived as described in Fig. 2 legend. Cell lines transfected with pEJ are shown at confluence (EJ/Gpt-2, *a*) and subconfluence (EJ/Gpt-3, *b*). Cell lines transfected with pEC are also shown at confluence (EC/Gpt-5, *c*) and subconfluence (EC/Gpt-1, *d*).

Detection of differences in the size of the oncogene product

In view of the above conclusion, new importance was attached to the previously detected slight variations in migration rates of the p21 proteins from different cells (Figs 1*b* and 2*b*). We therefore re-analysed the p21 proteins after shorter periods of metabolic labelling, which we expected would highlight these differences more clearly. Data shown in Fig. 4*a* indicate that the pEJ and pEC transfectants each exhibit two bands of p21. Kinetic labelling experiments indicate that in each case the more slowly migrating band behaves as a kinetic precursor to the more rapidly migrating band (manuscript in preparation). Comparable data on the p21 protein of v-Ha-*ras* previously indicated that the higher band underwent post-translational cleavage to yield its lower, more rapidly migrating partner[28].

Further examination of Fig. 4*a* reveals that the higher molecular weight p21 protein of the pEJ transfectant migrates slower than the higher molecular weight protein of the pEC transfectant and also that the lower molecular weight p21 of the pEJ transfectant migrates slower than the lower molecular weight p21 of the pEC transfectant. The relative migration rates of the these proteins, and the relationships we impute to them from kinetic data and previously published experiments[28] are indicated schematically in Fig. 4*a*.

As none of the p21 proteins seems to be phosphorylated to any extent (data not shown), the differences in migration between the pEC and pEJ proteins are most readily attributed to alterations in the number of amino acids or to changes in conformation. The data and the schematization of Fig. 4*a* may provide an explanation for the complexity of p21 proteins seen in normal and transformed bladder cells (Fig. 1*b*): the normal cells exhibit two bands, reflective of the expression of a proto-oncogene; the carcinoma cells appear to exhibit four bands, two being specified by the oncogene of these cells, and two by the normal, proto-oncogene of the other, homologous chromosome.

Genetic mapping of the functionally altered region of the oncogene

To determine whether the observed physical difference between p21 proteins reflected a functionally important change involved in the process of transformation, we set out to supplement these results with an independent series of experiments designed to localize genetically the regions of the oncogene that specify the altered migration rate of the protein and the change in gene function. These experiments depended on *in vitro* homologous recombination between clones of the two genes. The experimental design was to excise a restriction fragment out of the oncogene and use it to replace the homologous piece of the proto-oncogene. At the same time, the reciprocal construction was carried out by splicing the fragment of the proto-oncogene into the oncogene. These recombinant constructs were then tested for transforming ability in the transfection assay. We looked for the ability of a fragment of the oncogene to impart transforming activity when placed in the midst of a proto-oncogene clone, and conversely, in the reciprocal recombination, for the loss of activity when the corresponding proto-oncogene fragment was inserted into the oncogene clone. The constructions are shown schematically in Fig. 5. Following *in vitro* ligation, the recombinant clones were amplified and mapped to confirm their construction. Only then were they transfected to NIH 3T3 monolayers.

It was vital that we should be able to verify that the transforming clones were indeed chimaeras of mixed pEJ and pEC origin, rather than contaminants of one origin or the other. This was

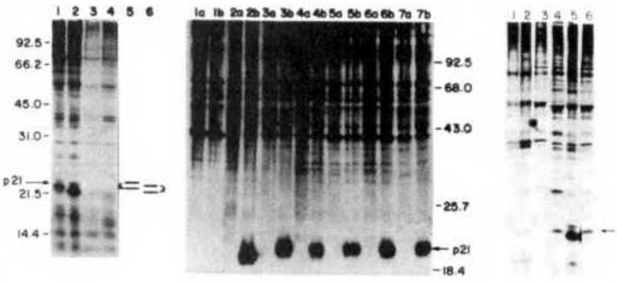

Fig. 4 Comparison of the mobility of p21 proteins encoded by the EJ bladder carcinoma transforming gene and its normal homologue. *a*, Immunoprecipitations from cells transfected with pEJ or pEC. Cells were metabolically labelled with ^{35}S-methionine for 3 h; cell lysates were prepared, immunoprecipitated and analysed as described in Fig. 1 legend. Cell lines were derived as described in Fig. 2 legend. Lysates from the cell line EJ/Gpt-3 (lanes 1, 3) and from the cell line EC/Gpt-1 (lanes 2, 4) were precipitated with the monoclonal anti-p21 antiserum Y13-238 (lanes 1, 2) or with non-immune serum (lanes 3, 4). Schematic diagrams (lane 5, EJ/Gpt-3; lane 6, EC/Gpt-1) show both the relative positions of the detected p21 bands and the relationships of those bands (arrows) based on kinetic data (not shown) and previously published experiments[28]. *b*, Analysis of the migration of p21 proteins immunoprecipitated from cells transfected with *in vitro* recombinants of the EJ oncogene (pEJ) and its homologous proto-oncogene (pEC). NIH 3T3 cells transformed with the EJ bladder tumour oncogene, its normal proto-oncogene, or recombinants between the two genes were first biologically cloned in 0.35% agar and then metabolically labelled with ^{35}S-methionine for 18 h. Lysates were prepared and immunoprecipitated (5×10^6 c.p.m. of TCA-precipitable counts) by a monoclonal antibody that detects the p21 encoded by Ha-MuSV but not the p21 encoded by Ki-MuSV (Y13-172)[25,32]. Dissolved immunoprecipitates were then resolved by electrophoresis in a 12% SDS-polyacrylamide gel. Lanes 1a–7a, no antibody; lanes 1b–7b, anti-Harvey p21 monoclonal antibody. Cell lysates were from: NIH 3T3 cells (lane 1); cells transformed with the proto-oncogene (the 3-kb *Sac*I fragment of the pEC proto-oncogene that has been activated by fusion with a retrovirus LTR transcriptional promoter described in ref. 35) (lane 2); cells transformed with the EJ oncogene (6.6-kb fragment in pBR) (lane 3); clone 511-74, transformed with the ligation of proto-oncogene 1-kb *Sac*I fragment to EJ oncogene 3-kb *Sac*I fragment (construction b2, Fig. 5) (lane 4); cells transformed with ligations of a fragment of the EJ oncogene extending from the *Xho*I site to the second *Bst*EII site to a clone of the proto-oncogene from which the homologous fragment had been removed (construction e2, Fig. 5) (lanes 5 and 6); and cells transformed with the ligation of the EJ oncogene to the left of the *Kpn*I site to the proto-oncogene to the right of this site (construction a2, Fig. 5) (lane 7). *c*, Analysis of the migration of the p21 proteins immunoprecipitated from cells transfected with the *in vitro* recombinant in which the 350-bp *Xma*I–*Kpn*I fragment of the pEJ oncogene clone was inserted into the corresponding region of the pEC proto-oncogene clone. Cells were metabolically labelled with ^{35}S-methionine for 3 h; cell lysates were prepared, immunoprecipitated and analysed as described in Fig. 1 legend. Cell lines EC/Gpt-1 and EJ/Gpt-3 were derived as described in Fig. 2 legend. The *in vitro* recombinant was constructed as described in Fig. 5 legend, part h2. The resulting construct was transfected as described in Fig. 2 legend and a transformed focus was picked and expanded. Immunoprecipitations were performed with non-immune serum (lanes 1–3) or with the monoclonal antiserum (Y13-238) which precipitates the Ha-MuSV p21 (lanes 4–6). Cell lysates were prepared from EJ/Gpt-3 (lanes 1 and 4); EC/Gpt-1 (lanes 2 and 5); and the *Xma*I–*Kpn*I recombinant transfected cell line (lanes 3 and 6).

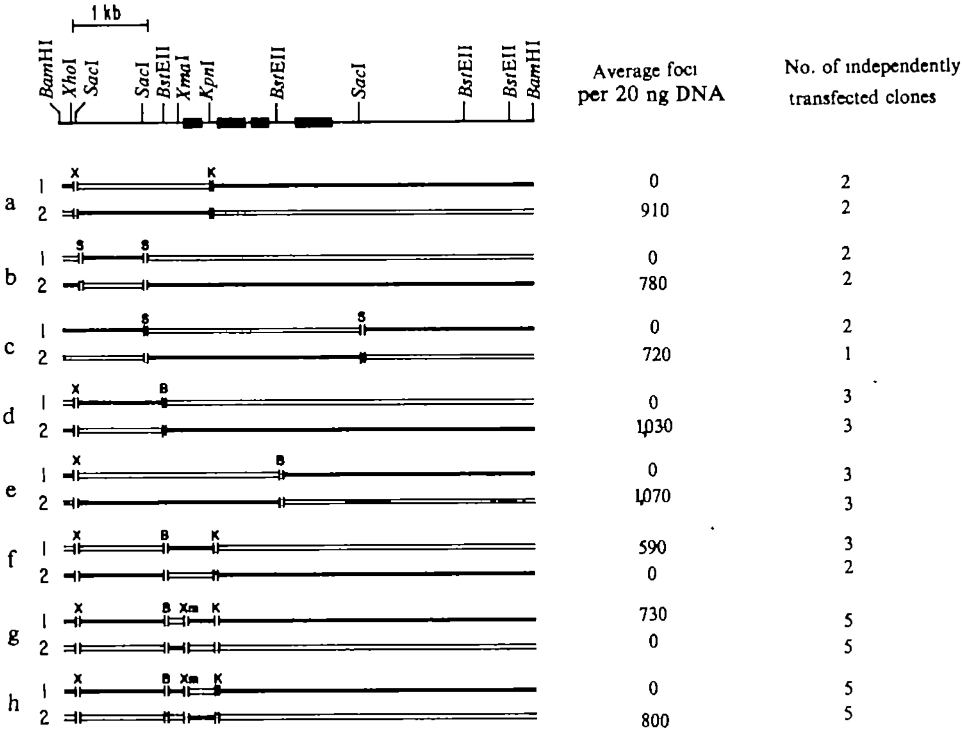

Fig. 5 Transfection data and structures of *in vitro* genetic recombinants between the molecular clones of the EJ transforming gene (pEJ) and its normal cellular homologue (pEC). The restriction map shows the cleavage sites for various enzymes within the 6.6-kb *Bam*HI insert in pBR322. All sites specific for the enzymes are shown except for *Xma*I which cuts in several other places which have not been well characterized. The site shown is the only *Xma*I site between the first *Bst*EII site and the *Kpn*I site The solid boxes on the map show the locations of coding exons pEJ/pEC chimaeras are shown, with segments derived from pEJ shown as solid bars and segments from pEC shown as open bars. pEJ and pEC were cleaved with the indicated enzymes either to completion or in a partial digest as required to obtain each indicated fragment The products were separated by electrophoresis through 1.2% agarose and eluted by melting in NaI and adsorbing to glass beads. The fragment containing pBR322 was then treated with calf intestinal phosphatase. The indicated fragments were joined either with the enzyme T4 DNA ligase or in a mock ligation without enzyme. Constructs a–e were made in bimolecular ligations. Constructs in f were made by mixing the three fragments simultaneously and in g and h by mixing the four fragments simultaneously The ligation mixtures were directly transformed into the HB101 strain of *Escherichia coli*. Only when colonies from mock ligations were less than 2% of the ligations were colonies analysed for the presence of clones with appropriate restriction maps; 20 ng of each clone were transfected to NIH 3T3 cells as described in Fig. 2 legend and then carried without selection until foci were visualized in 10–14 days. Results of the transfections are shown in the first column. The second column shows the number of independent bacterial colonies screened and then transfected into NIH 3T3 cells.

done in three ways. In the simpler constructions, involving ligations of two fragments at a time, we verified results obtained with amplified recombinant clones by directly transfecting the unamplified products of ligation reactions and of mock ligations containing isolated fragments not treated with the ligase. A second confirmation depended on the fact that the plasmids pEJ and pEC contained their respective cellular genes inserted in the pBR322 plasmid vector in opposite orientations. Thus, we could learn the origin of one parent of a recombinant by diagnostic restriction digests of the flanking plasmid regions. Since contaminating pEC could itself not give a false positive result (as it is not transforming), any active clone carrying proto-oncogene flanking sequences must have arisen as a consequence of acquisition of portions of the transforming gene. Finally, we confirmed all of our results with several independent clones obtained from a ligation reaction. The products of a ligation were used only if mock ligation of the same fragments gave no more than 2% of the bacterial colonies seen on use of the DNA ligase.

The results of transfecting the recombinant clones are summarized in Fig. 5. As can be seen, we ultimately identified a genetic region 350 nucleotides long which, when transferred from the oncogene to a corresponding region in the proto-oncogene, is able to impart activity to the latter. This region extends from the first *Xma*I endonuclease site to the *Kpn*I site (Fig. 5); 55% of this region consists of the first coding exon, 10% is 5′ to the coding region and 35% is part of the first intron.

Detection of differences in size of the gene product from the *in vitro* recombinants

In experiments described above, we had identified a difference in the migration of the p21 protein encoded by the oncogene and the proto-oncogene. Having now determined a short region of the gene which contained the transforming lesion, it became important to ascertain whether the region also contains the specificity for the altered protein size. We therefore carried out immunoprecipitations on cells transfected with the products of the *in vitro* recombinants. As seen in Fig. 4*b*, the protein brought down in lysates from *Xho*I–second *Bst*II site, *Sac*I–*Sac*I, and *Xho*I–*Kpn*I recombination transfectants all co-migrate with the EJ protein and have a mobility which differs from that of the EC protein. Similarly, Fig. 4*c* demonstrates this result for the *Xma*I–*Kpn*I recombinants. The lysates analysed in panel 4*b* were from cultures that were labelled for 18 h, resulting in high levels of label in the lower molecular weight forms of the p21, and undetectable amounts of label in the kinetically unstable higher molecular weight forms. We conclude that the phenotypes of oncogenic transformation and altered electrophoretic migration co-segregate, and the two are encoded by the same 350-bp segment of DNA. As indicated below, the altered migration rate is probably a reflection of a functionally important alteration of the protein.

Nucleotide sequence of the transforming lesion

Having identified a short fragment of biological significance, we then sequenced this region of the oncogene and the proto-oncogene. Figure 6 compares the sequences of the two genes in this segment obtained by sequencing both strands. The DNA sequence described in the figure was obtained by the forward and backward dideoxy DNA sequencing technique of Seif *et al.*[29] and by the chemical procedure of Maxam and Gilbert[30].

The difference between the two segments is in the p21 encoding region of the first known exon, specificially 60 nucleotides from the *Xma*I cleavage site. It occurs in a triplet that encodes glycine in the normal rat (M. Ruta *et al.*, unpublished data) and human c-Ha-*ras* genes. The sequence observed in the EJ oncogene causes conversion to a valine. As we discuss below, we believe that this alteration is responsible for the alteration in function of the p21 protein, and for the oncogenic activation of the c-Ha-*ras* gene that occurred in the EJ bladder carcinoma.

Alteration of a diagnostic restriction endonuclease cleavage site

A second independent consequence of the single base change was the alteration in the cleavage sites of two different site-specific endonucleases. The sequence GCCGGC occurs in the proto-oncogene, and thus represents the recognition site of the endonuclease *Nae*I. It also contains the CCGG recognition site of the endonuclease *Hpa*I. Both of these are changed in the oncogene, the equivalent sequence of which reads GCCGTC. The *Nae*I endonuclease is the more useful of the two since it cleaves DNA less frequently, and we used it to independently verify the two sequences. As expected, the pEC clone exhibited one more cleavage site in its inserts than its pEJ counterpart (data not shown). Perhaps more useful was the retrospective verification of the *in vitro* recombinant clones. The allele specifying transformation and abnormal p21 migration was seen to precisely co-segregate with the allele disallowing *Nae*I cleavage at this site (data not shown).

Discussion

Use of gene transfer and molecular cloning had previously made it possible to localize an important lesion of the EJ bladder carcinoma genome to a 6.6-kb DNA segment constituting only 10^{-6} of the genetic content of the tumour cell. The segment appears to contain the entire transforming activity previously associated with the whole tumour cell DNA. This oncogene is an important, but perhaps not the sole, determinant of the transformed phenotype of these carcinoma cells. Sequence hybridization showed that this oncogene was related in structure to a similar sequence existing in the normal cellular genome[12–15]. It appeared that the oncogene arose from the activation of these normal sequences, and that this activation occurred during the process of carcinogenesis which led to formation of the original EJ carcinoma. Experiments described in this report were designed to resolve and define the critical differences that distinguish the oncogene from its proto-oncogene precursor.

It was apparent that a definition of these differences could not be achieved by simple comparison of the sequences of the two genes. As the oncogene and its normal proto-oncogene counterpart sequence were derived from the DNAs of separate individuals, most sequence differences might reflect naturally occurring, silent polymorphisms at this locus. Other sequence differences could be consequences of mutational insults suffered during carcinogenesis, which were silent functionally and thus of no importance to the activation process. These considerations caused us to undertake the *in vitro* recombination experiments in order to narrow the area of functional importance to a segment so small that it would probably contain few if any silent mutations. Only after narrowing the functional segment to 350 bp did we initiate DNA sequence studies.

The sequence difference that we observed in this region could have only one consequence for the structure of the p21 protein—a simple amino acid substitution leading to the replacement of a glycine by a valine residue. This substitution appears to represent the critical agent of the conversion of the proto-oncogene into an active oncogene.

Fig. 6 Comparison of the DNA sequence of the molecular clone of the EJ transforming gene (pEJ) and its non-transforming cellular homologue (pEC). Sequence data between the restriction enzyme sites *Xma*I and *Kpn*I are shown (see Fig. 5). The coding DNA strand is printed as is the inferred amino acid sequence. For coding regions where pEJ and pEC differ, both sequences are indicated. Sequences were determined by the forward and backward dideoxy DNA sequencing technique of Seif *et al.*[29] and by the chemical procedure of Maxam and Gilbert[30].

Such a simple substitution might not be expected to effect a profound change in the function of the p21 protein. However, several considerations seem to confer importance on the structural alteration. The first stems from comparison of this domain of p21 encoded by the human c-Ha-*ras*-1 gene, the rat c-Ha-*ras*-1 gene (Ruta *et al.*, unpublished results) and the v-Ha-*ras* oncogene of Harvey sarcoma virus[31]. The 37-residue long amino acid sequences encoded by the first exons of the two cellular genes are identical, indicating strict evolutionary conservation of this region. However, analysis of the Harvey sarcoma virus oncogene reveals that it deviates from its direct rat cellular antecedent in only one position in this domain, a glycine to arginine conversion at precisely the same residue that is altered in the EJ oncogene. Thus, we speculate that alteration of this critical residue was important both in the activation of the v-Ha-*ras* gene from its rat cellular precursor, and in the activation of the EJ bladder oncogene from its normal human counterpart. Moreover, a similar alteration may have been significant in the oncogenic activation of another member of the *ras* gene family, the v-Ki-*ras* gene of Kirsten murine sarcoma virus. The Kirsten transforming gene is closely related to the v-Ha-*ras* gene[32]. The only difference between the p21 of v-Ki-*ras* and that of v-Ha-*ras* in the first 36 amino acids is at position 12, where the residue in Kirsten is serine[33], again at precisely the same site as altered in the EJ and Harvey sarcoma virus encoded p21s. While sequence information is not available on the cellular homologue of v-Ki-*ras*, we speculate that a conversion from a glycine to a new amino acid residue at position 12 may also have been involved in the activation of this *ras* oncogene.

A second consideration stems from examination of the specific amino acid changes observed in these cases. In both instances, glycine is replaced by an amino acid having a relatively bulky side chain. Glycine is an anomaly among the 20 amino acids, because it lacks a side chain. Thus, it is able to participate in extremes of bending and folding of the polypeptide backbone and is the strongest breaker of α-helices[34]. Thus, replacements of glycine by valine or arginine represent abrupt changes in the local stereochemistry of a protein.

We speculate that the loss of glycine at residue 12 causes a significant change in an essential domain of the p21 protein. One consequence of this change may be a conformational shift of the protein, leading in turn to the aberrant electrophoretic migration or processing of the p21 proteins. A second, more important consequence is a profound effect on the function of the p21 protein. This alteration probably affects interaction of the p21 with cellular targets. A precedent exists for other single amino acid changes having profound effects on cellular and organismic physiology. The most well known of these is the sickle-cell syndrome, in which a glutamine to valine conversion affects the solubility of haemoglobin within erythrocytes.

The importance we attach to alteration of protein structure would seem to contradict a series of experiments of recent years that indicate up-regulation as the pivotal event in carcinogenesis. These experiments include the activation of the *myc* proto-oncogene occurring during leukaemogenesis of avian retroviruses[35,36]; and the demonstration that *in vitro* fusion of a retroviral long terminal repeat (LTR) promoter and a cellular proto-oncogene results in an actively transforming gene[20,37,38]. These latter experiments are particularly germane, since some of them demonstrate activation of clones of the rat and human c-Ha-*ras* proto-oncogenes[20,38]. It is unlikely that the protein-encoding sequences of these c-Ha-*ras* genes have undergone any structural changes during construction of these viral–cellular chimaeras. Rather, it appears that the only essential difference between the proto-oncogenes and their LTR-activated counterparts lies in rates of expression. This means that the *ras* proto-oncogene can be activated by a second independent mechanism, in principle as effective in creating an oncogene as the one described here.

We point out that oncogenes of other tumours have also been traced to *ras* genes. Specifically, colon and lung carcinomas (ref. 15 and M. McCoy, J. J. Toole, E.H.C. and R.A.W., in preparation) as well as fibroblastic tumours (L. Parada and R.A.W., unpublished results) have been found to carry oncogenes derived from activation of cellular Ki-*ras* genes. As discussed above, the N-terminal regions of the Ha-*ras* and Ki-*ras* proteins are extremely similar, and the Ki-*ras* proteins of many of these tumours also exhibit aberrant electrophoretic migration rates (manuscript in preparation). We predict that activation of many of these other oncogenes will depend on structural alterations very similar to those reported here.

Most amino acid sequence alterations are either neutral or deleterious to protein function. Few are able to actively potentiate the normal functions of a protein. We suggest that only a small number of sites on the p21 protein can be altered in a fashion leading to oncogenic activation. Most mutations will affect other residues whose alteration will be unproductive for oncogenic conversion. The target for oncogenic conversion may therefore be exceedingly small, and may even be confined to the Gly-12 codon. In such a case, the restriction site for *NaeI*, which totally spans that codon, may provide an ideal diagnostic tool for detecting a critical change in the genome.

The present data suggest that the alteration of one nucleotide in one bladder cell leads to the creation of an activated oncogene. There are three possible point mutations at this position, and it is perhaps not coincidental that the G-T transversion observed here is precisely that mutation favoured by many suspected bladder carcinogens[39]. The oncogene resulting from this mutation was probably an important determinant in the subsequent outgrowth of a lethal neoplasm. The point mutation implicated as a central event in this oncogenic transformation represents the first demonstration of a lesion in cellular DNA whose occurrence is directly related to the carcinogenic process.

We thank Dr James G. Rheinwald and Terry O'Connell (Sidney Farber Cancer Institute) for preparing cultures of normal human bladder cells; Drs B. Ballou and T. Hakala for the bladder biopsy; Dr Mark Furth for providing monoclonal anti-p21 antisera; R. Kooler and L. Donehower for help in sequencing; R. Chipperfield for assistance in constructing recombinant clones; Dr G. Zieve for photographing cell lines; Dr J. Essigmann for helpful discussions; Dr M. Ruta for communicating data before publication and S. Posner for secretarial assistance. This work was supported by grants CA26717, CA31649 and CA17537 from the USNCI and by a grant from the Whitehead Institute for Biomedical Research.

A point mutation is responsible for the acquisition of transforming properties by the T24 human bladder carcinoma oncogene

E. Premkumar Reddy, Roberta K. Reynolds, Eugenio Santos & Mariano Barbacid

Laboratory of Cellular and Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

The genetic change that leads to the activation of the oncogene in T24 human bladder carcinoma cells is shown to be a single point mutation of guanosine into thymidine. This substitution results in the incorporation of valine instead of glycine as the twelfth amino acid residue of the T24 oncogene-encoded p21 protein. Thus, a single amino acid substitution appears to be sufficient to confer transforming properties on the gene product of the T24 human bladder carcinoma oncogene.

DNA-MEDIATED gene transfer techniques have made it possible to identify the presence of dominant transforming genes (oncogenes) in a variety of human tumours (for review see ref. 1). Although only a small number of human tumour DNAs have been shown to be capable of transforming normal cells in transfection assays, oncogenes have been detected in tumours representative of each of the major forms of human cancer[2–8]. To date, more than 10 different human oncogenes have been identified. One of them, present in T24 and EJ bladder carcinoma cell lines, has been isolated by molecular cloning techniques[8–10]. Preliminary characterization of this oncogene has revealed that it is small (less than 4.6 kilobase, kb), and that it has not undergone major genetic rearrangements[9–11]. Comparative analysis of this bladder carcinoma oncogene with retroviral transforming (*onc*) genes has revealed that an internal fragment of the T24 oncogene is closely related to the *onc* genes of

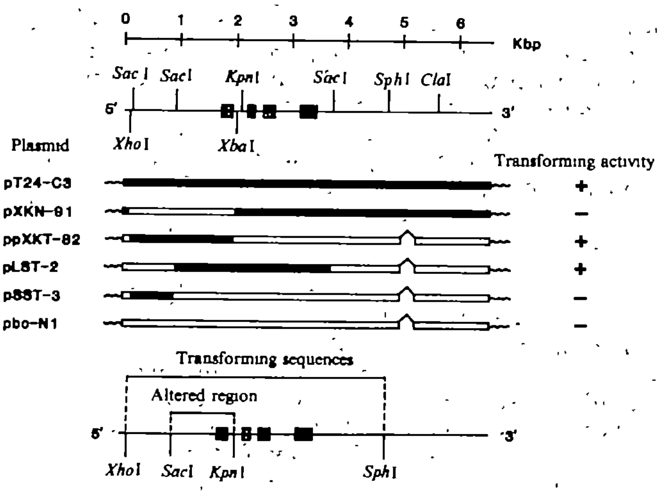

Fig. 1 Location of the region of the c-*has*/*bas*-1 gene that underwent the genetic alterations that led to the activation of the T24 oncogene. Hybrid plasmids containing sequences derived from pT24-C3 (■) and pbc-N1 (□) were tested for their biological activity. pT24-C3, pXKT-82 and pLST-2 transformed NIH 3T3 cells in transfection assays[8], with specific transforming activities of 5×10^4, 1×10^4 and 0.6×10^4 ffu pmol^{-1}, respectively. In contrast, pbc-N1, pXKN-91 and pSST-3 exhibited no transforming activity. The hatched boxes located within the restricted endonuclease map shown in the top of the figure represent the predicted exons of the T24 oncogene and its normal homologue, the c-*has*/*bas*-1 gene. Deletions (/\), and plasmid sequences (〰), are also indicated in the diagram. See text for definition of the regions encompassing the transforming sequences and the activated domain of the T24 oncogene.

Harvey and BALB murine sarcoma viruses (designated v-*has* and v-*bas*, respectively)[11–13]. Characterization of human DNA sequences homologous to v-*has* and v-*bas* has demonstrated that the normal c-*has*/c-*bas*-1 gene is in fact an allele of the T24 oncogene[11–14]. Moreover, we found that these genes, despite their different biological properties, were indistinguishable by both heteroduplex and restriction enzyme analysis[11–13]. In an effort to understand the molecular events involved in human carcinogenesis, studies were undertaken to determine the number and nature of the genetic alterations that have resulted in the activation of the T24 human bladder carcinoma oncogene.

A domain within the T24 oncogene responsible for its activation

Previously, we have reported that a plasmid (pT24-C3) known to contain a 6.6-kb *Bam*HI fragment of T24 cellular DNA was capable of transforming NIH 3T3 mouse cells with a specific activity of 5×10^4 focus-forming units (ffu) per pmol. A restriction endonuclease map of this DNA fragment is depicted in Fig. 1. The transforming activity of this molecule was localized to a region within the 4.6-kb *Xho*I–*Sph*I DNA fragment based on the observations that cleavage with these two restriction endonucleases did not affect the transforming activity of pT24-C3 (ref. 11). To establish the region of the normal human c-*has*/*bas*-1 gene that underwent the genetic alterations leading to its malignant activation in T24 bladder carcinoma cells, we constructed a series of plasmids in which fragments of the T24 transforming gene were substituted with the homologous normal sequences of c-*has*/*bas*-1. In reciprocal experiments, regions of the normal c-*has*/*bas*-1 gene were replaced by the corresponding domains of its transforming allele. Figure 1 summarizes the plasmids constructed in the present studies as well as their respective biological activities. Substitution in pT24-C3 of a DNA fragment located between the *Xho*I and *Kpn*I cleavage sites by normal sequences, completely abolished its transforming activity. In contrast, replacement of the normal *Xho*I–*Kpn*I region of pbc-N1, a plasmid that contains the 6.4-kb *Bam*HI DNA clone of the normal human c-*has*/*bas*-1 gene, by the corresponding domain of pT24-C3, generated a plasmid (pXKT-82) that transformed NIH 3T3 mouse cells with an efficiency of 10^4 ffu pmol^{-1}.

Two additional plasmids were generated by replacing the internal 0.7-kb and 3.0-kb *Sac*I DNA fragments of pbc-N1 by the corresponding regions of the T24 oncogene. As shown in Fig. 1, only the latter plasmid (pLST-2) was able to induce malignant transformation on transfection to NIH 3T3 cells. These results, taken together, establish that the genetic alterations that activated the T24 oncogene are located within the 0.9-kb *Sac*I–*Kpn*I DNA fragment of pT24-C3 DNA.

Fig. 2 Comparative sequence analysis of the 0.93-kb *Sac*I–*Kpn*I DNA fragment of the T24 oncogene and its normal human homologue c-*has*/*bas*-1. The upper line shows the sequence of the T24 oncogene proceeding in the 5′ to 3′ direction with respect to the polarity of the closely related v-*has* and v-*bas* retroviral mRNAs. The corresponding sequence of the 0.93-kb *Sac*I–*Kpn*I DNA fragment of c-*has*/*bas*-1 has also been determined and found to be identical to that of the T24 oncogene with the exception of the nucleotide located at position 653, where we detected a G instead of a T. These nucleotide chains result in the incorporation of glycine, instead of valine, at position 12 in the p21 protein coded for by the c-*has*/c-*bas*-1 gene. Termination codons are indicated (···). The nucleotide sequence analysis was performed according to the procedures of Maxam and Gilbert[23].

Fig. 3 Predicted amino acid sequence of the first exon of the normal human c-*has*/*bas*-1 gene and its transforming allele, the T24 oncogene. Comparison with the first 37 amino acids predicted for the p21 proteins coded for by Harvey-MSV[15] and Kirsten-MSV[18]. The letter code for the amino acids is: A, Ala; D, Asp; E, Glu; F, Phe; G, Gly; H, His; I, Ile; K, Lys; L, Leu; M, Met; N, Asn; P, Pro; Q, Gln; R, Arg; S, Ser; T, Thr; V, Val; and Y, Tyr.

Comparative sequence analysis of the 0.9-kb *Sac*I–*Kpn*I DNA fragments of pT24-C3 and pbc-N1

The nucleotide sequence of the 0.9-kb *Sac*I–*Kpn*I DNA fragments of the T24 oncogene and its normal homologue was next established. To our surprise there was only a single (nucleotide) change, located at position 655 from the *Sac*I cleavage site. Figure 2 shows that the guanosine residue present in the normal c-*has*/*bas*-1 gene has been changed into a thymidine residue in the T24 oncogene. Thus the activation of the c-*bas*/*ras*-1 gene in T24 human bladder carcinoma cells was caused by a single point mutation.

The mutated guanosine residue was found to be part of the hexanucleotide sequence GCCGGC, which is specifically recognized by the restriction endonuclease *Nae*I. Thus, we used this enzyme to verify the results obtained by nucleotide sequence analysis. We observed that *Nae*I cleaved the 6.4-kb *Bam*HI insert of pbc-N1 five times, yielding four internal DNA fragments, of sizes 0.2, 0.4, 0.6 and 0.9 kb. In contrast, digestion of pT24-C3 with *Nae*I yielded only three internal fragments, of sizes 0.2, 0.6 and 1.3 kb (data not shown). The loss of the *Nae*I cleavage site within the 1.3-kb internal fragment confirms the nucleotide sequence shown in Fig. 2.

Heteroduplex analysis of the T24 oncogene and its normal allele with v-*has* and v-*bas* had indicated that the putative coding sequences of the human genes are distributed among four exons, of which only the first one lies within the 0.9-kb *Sac*I–*Kpn*I fragment[11,14]. We have sequenced the entire coding region of the T24 oncogene and identified the four exons by comparison of these sequences with those of v-*has*[15] and v-*bas*[16]. This sequence analysis demonstrated that the first exon ends at position 731 from the *Sac*I cleavage site (Fig. 2). At this position, we detected the consensus donor splice sequence AGAGG[17]. Thus, in agreement with previous heteroduplex analysis and restriction enzyme data[11,14], the first exon of the T24 oncogene contained the coding information for 37 amino acids extending from position 621 to 731. These observations located the mutated G residue at the second base of a triplet coding for glycine, the predicted twelfth amino acid residue of the normal human p21 protein. Substitution of this guanosine residue for thymidine results in the change of the glycine-coding triplet GGC to GTC, which codes for valine. Thus, a single amino acid substitution (Gly→Val) seems to be sufficient to confer transforming properties to the gene product of the T24 human bladder carcinoma oncogene.

A common genetic alteration in human and retroviral transforming genes

The amino acid sequences of Harvey and BALB-MSV-encoded p21 proteins have been identified by nucleotide sequence analysis of their corresponding *onc* genes, v-*has* and v-*bas*, respectively[15,16]. Comparison of the first 37 amino acids of the p21 protein coded for by the normal c-*has*/*bas*-1 human gene with their retroviral counterparts shows complete identity except at position 12, the same amino acid residue that is altered in the T24 oncogene (Fig. 3). Whereas arginine is present in Harvey-MSV p21[15], lysine was found in BALB-MSV p21[16]. Interestingly, the normal rat homologue of human c-*has*/*bas*-1, the gene that presumably recombined with Moloney-MuLV to generate Harvey-MSV, also possesses glycine at position 12 (M. Ruta, personal communication). These results suggest that mutations affecting the coding properties of the twelfth codon of normal c-*has*/*bas*-1 genes may be sufficient for the acquisition of malignant properties.

Recently, Tsuchida *et al.* have also reported the nucleotide sequence of v-*kis*, the *onc* gene of Kirsten-MSV[18]. When the first 37 amino acids of the deduced sequence of Kirsten p21 were compared with those of c-*has*/*bas*-1, only two changes were detected: Gly→Ser in position 12, and Glu→Gln in position 37. Thus, it is possible that changes in the glycine residue at position 12 may have also activated c-*kis* genes. This hypothesis would predict that another human transforming oncogene, present in a large variety of human carcinomas and known to contain the human c-*kis*-2 gene,[5,6,8,12,14,19] has been activated by the same mechanism that originated the T24 oncogene.

Activation of the human c-*has*/*bas*-1 gene: a qualitative or quantitative mechanism?

That each of the known p21 transforming proteins has a different amino acid at residue 12 suggests that their malignant properties are the result of the elimination of the glycine residue present in their normal counterparts, rather than due to a specific transition from one type of amino acid residue to another. Glycine residues are known to alter the α-helical structure of proteins. We compared the predicted secondary structures of the p21 proteins coded for by the T24 oncogene and its normal human homologue using the computerized method of Garnier *et al.*[20]. Such an analysis revealed that the N-terminal region of the c-*has*/*bas*-1-encoded p21 protein contains two α-helical regions of 10 and 13 amino acids joined by a hinge region of 7 amino acids that provides flexibility for folding. When the glycine at position 12 is replaced by valine in the transforming p21 protein, the size of the hinge region decreases to a stretch of two amino acids, resulting in an increased helical content of the N-terminal region of this protein. This change should result in the prominent projection of the N-terminal domain of transforming p21 proteins away from the central core of the molecule.

The biological significance of the structural alteration of human and retroviral p21 transforming proteins remains to be determined. Shih *et al.* have recently reported that the Harvey-MSV p21 protein is processed before its association with membranous structures[21]. Whether the presence of a glycine residue in position 12 confers on the normal cellular p21 protein a configuration that affects either its processing or its association with putative cellular targets remains to be determined. Whatever the mechanism might be, our findings indicate that the difference between the normal c-*has*/*bas*-1 and the T24 oncogene-encoded p21 proteins is of a qualitative nature.

However, it is also possible that quantitative alterations in the expression of the normal p21 protein induce malignant transformation. Chang *et al.* have shown that the normal c-*has*/*bas*-1 can transform NIH 3T3 mouse cells when this gene comes under the regulatory influence of a retroviral LTR[22]. In this case high levels of normal p21 protein can be detected in the transformed cells. Thus it is possible that increasing amounts of normal p21 protein may overcome the structural limitations imposed by the presence of a glycine residue at position 12. However, the possibility that over-expression of the normal c-*has*/*bas*-1 genes may induce morphological transformation by a different mechanism than that of their transforming counterparts cannot be ruled out at present.

Implications

The present studies have located the genetic changes leading to the activation of the T24 bladder carcinoma oncogene within a 0.9-kb *Sac*I–*Kpn*I DNA fragment of the human c-*has*/*bas*-1 gene. This region contains some 5′ putative regulatory sequences, as well as the first exon (Fig. 2). Comparative sequence analysis of these 0.9-kb DNA fragments derived from the T24 oncogene and its normal counterpart revealed a single base pair difference: a point mutation (G→T) within the exon sequences that led to the substitution of a glycine residue in the normal c-*has*/*bas*-1 gene-encoded p21 protein to a valine residue in the corresponding translational product of the T24 oncogene. These results, taken together, indicate that a single point mutation was responsible for the activation of this oncogene in T24 human bladder carcinoma cells.

These findings may have important practical applications. The mutated guanosine residue is part of a sequence (GCCGGC) recognized by the restriction endonucleases *Nae*I (GCCGGC), *Hpa*II (CCGG) and *Msp*I (CCGG). The G→T change observed in the T24 oncogene eliminated the cleavage site for these three enzymes. Neither *Nae*I nor *Hpa*II appear to cleave this sequence in human DNA, probably due to DNA methylation. However it is possible that *Msp*I, which recognizes the CCGG sequence whether methylated or not, could be used for the screening of human DNAs for the presence of T24-like oncogenes. Similarly, antibodies capable of specifically recognizing the altered domain of transforming p21 proteins may also be used to detect activated c-*has*/*bas* genes.

Demonstration that a single genetic change can activate a human transforming gene poses the dilemma as to how to relate these observations with the widely accepted multi-stage model for the development of human neoplasias. It is possible that activation of the T24 oncogenes may represent a late, irreversible step in oncogenesis. Support for this hypothesis comes from the fact that NIH 3T3 mouse cells, the cells used to identify this oncogene, are thought to be pre-neoplastic rather than normal cells. However, the possibility that this oncogene may have a role in the onset of certain human cancers cannot be excluded at present.

Development of biochemical and immunological reagents capable of specifically detecting the presence of the T24 bladder carcinoma oncogene (or its gene product) in both naturally and experimentally induced neoplasms should help to define the role of this dominant transforming gene in carcinogenesis.

We thank Richard Feldmann for help in the computer analysis of the p21 proteins, Anne V. Lauver and Linda K. Long for technical assistance, and S. A. Aaronson for support.

UV observations of TT Arietis and the magnetic rotator hypothesis

R. F. Jameson, M. R. Sherrington, A. R. King & J. Frank

Astronomy Department, University of Leicester,
Leicester LE1 7RH, UK

TT Arietis, one of the brightest cataclysmic variables, $m_v \sim 10.2 \rightarrow 11.0$, is usually classed as a novalike variable, but after a recent dip in brightness to $m_v \sim 14.5$, Krautter *et al.*[1] suggested it to be a dwarf nova in an extended high state. Photometric light curves[2–4] generally show a sinusoidal light variation with a period of 0.1329 days and no eclipses[5]. Cowley *et al.*[6] have measured radial velocity curves and find a period of 0.13755 days. We have made[7] IR measurements of the system from which we deduce a distance for TT Ari of 100 ± 20 pc based on a colour change for the system from V to K of +0.4 while the system is faint to $V-K=-0.17$ when brighter. The red colour is caused by dilution of the primary 2.2-μm light by the light of the secondary, giving $m_K = 11.75^{+0.45}_{-0.25}$ for the secondary star; Bailey's method[8] then leads to the distance. The sinusoidal light variations have generally been interpreted as due to a hot spot on the edge of an accretion disk. Since good quality IUE spectra can be made with exposure times of about 15 min, we decided to observe as many IUE spectra as possible round the binary period with a view to studying the behaviour of the hot spot at UV wavelengths. We now report that the variations at these and X-ray wavelengths round the orbital cycle rule out a hot spot/accretion disk model for TT Ari. Instead we propose that it has a magnetized white dwarf primary rotating with the photometric period of 0.1329 days.

Four short and four long wavelength low dispersion spectra were obtained with the IUE satellite spectrometer on 9 January, 1982. Between each exposure the fine error sensor (FES) was used to measure the white light variation of TT Ari. The spectra taken nearest to maximum light, are shown in Fig. 1, together with an optical spectrum measured by M. J. Ward with the Anglo Australian Telescope. Although the spectra appear noisy, most of the features are repeatable from one spectrum to the next. The strongest features are: Lyα 1,216 e (geocoronal?); N V 1,238 a; Si IV 1,393 a; C IV 1,549 e (2.9); He II 1,640 a; and Mg II 2795 e (2.1) where 'a' denotes absorption, 'e' emission and the number in parentheses the variation in line strength (maximum/minimum). The variation of the emission lines roughly follows that of the continuum variation. Regions as free as possible of absorption or emission lines were used to measure the continuuum light variations. The continuum was averaged over a bandwidth of 50 Å. The only significant errors in the measurements are due to the photometric accuracy of the IUE cameras, namely ≤ ±10%.

Figure 2 shows the four point continuum light curves at 1,265, 1,700, 2,110, 2,510 and 3,010 Å, together with the nine point white light FES light curve. The amplitude of the white light curve corresponds to $m_v = 11.86 \rightarrow 12.36$; thus TT Ari was unusually faint. The solid curves are an attempt to fit a curve of the same shape as the white light curve but with variable amplitude through the UV points. The main difficulty in getting a good fit to the UV points is that the FES points represent ~1 min of integration and are thus prone to the flickering whereas the UV points result from spectra with 15-min exposure times. Whichever numbers are used for the amplitude of the variations the trend is clear; maximum amplitude being found for white light and the hard UV with a minimum variation in between at 3,010 Å.

0028–0836/82/450152—04$01.00

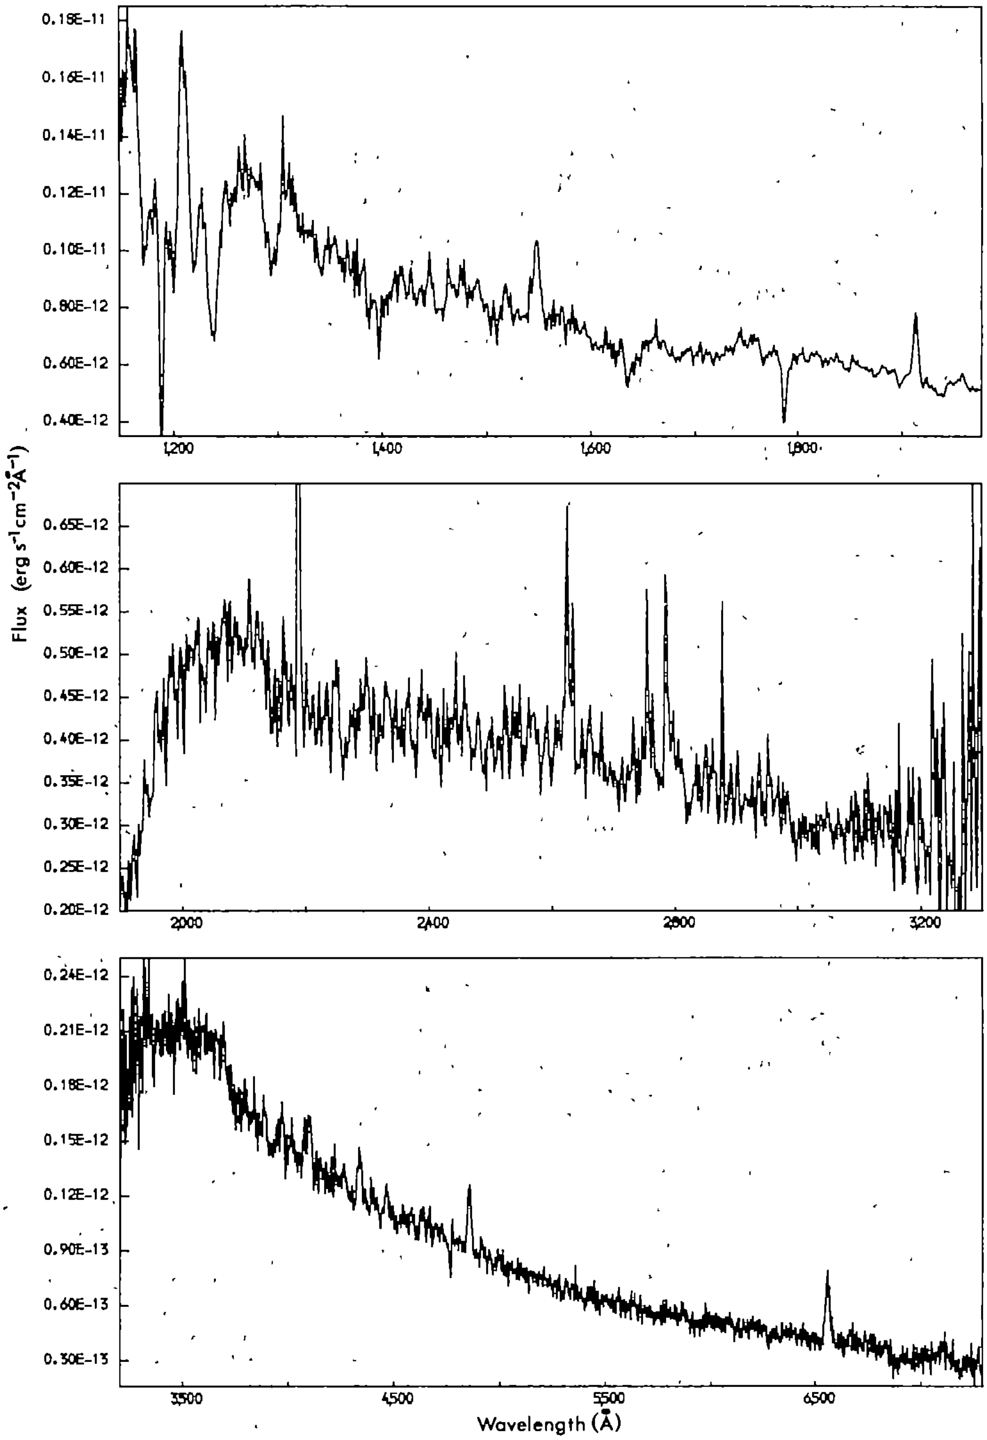

Fig. 1 The short and long wavelength IUE spectra together with the optical spectrum of TT Ari.

The FES curve apparently shows two maxima within the photometric period of 3 h 11 min making it not immediately recognizable as a typical light curve for TT Ari. This is not surprising remembering that there are only nine points (each of ~1 min integration) and that TT Ari shows considerable flickering. The larger of these two maxima can, however, be identified as the usual maximum since its epoch fits with the photometric period to some optical observations carried out in November 1981. A secondary maximum is also apparent in some of the published light curves. Ideally observations should have continued for two or more periods but this was not possible since the IUE satellite was beginning to overheat in this pointing direction. Also the 20 min preparation time needed for the IUE cameras makes it impossible to improve the time resolution without resorting to 'trailed' spectra which are difficult to analyse.

The reason for this changing amplitude can be seen from Fig. 3 which shows the five UV wavelengths together with *U*, *B* and *V* points derived from the FES counts and the known colours and changes in colours, taken from ref. 2. It is clear that the spectrum of TT Ari has two components, an unchanging black-body-like component which peaks near 3,000 Å, and a rather flat (in frequency units) component which causes the variability. This flat spectrum must also turn down in the optical region. The change between the two spectra is approximately the same (~20 mJy) at each wavelength, suggesting the source of the flat spectrum is seen at differing aspects.

It is possible allowing for errors that the whole spectrum from 5,500 to 1,265 has a single amplitude of ~1.4 mag. However, the shape of the spectrum lends credence to a change of amplitude with wavelength. It is just conceivable that a disk atmosphere model might explain the whole observed spectral shape from 5,500 to 1,265 Å; this would then all have to vary with the single amplitude. However, the correlation of the UV and X-ray variation makes such a model implausible.

These observations cannot be explained by a hot spot on the edge of an accretion disk. Large variations (amplitude 1.53) are seen at $\lambda = 1,265$ Å; radiation at this wavelength would be expected to arise close in to the white dwarf and not from the edge of an accretion disk. Any modulation by the hot spot is the more difficult when it is remembered that since there are no eclipses the inclination (i) must be <60°. Finally X-ray observations by Jensen *et al.*[9] rule out a hot spot. They find that 0.1–4 keV X rays vary over the orbital period with an amplitude of ~1.5 in a manner similar to the optical variation which they measured simultaneously. They also find X-ray flickering which correlates with the optical flickering, the latter preceding the X-ray flickering by $\gtrsim$40 s. This strange result may be due to a quasi-periodic flickering time of ~40 s found by Mardirossian *et al.*[3]. Clearly, the X-ray variation also rules out a model in which the variations arise from a non-axisymmetric atmosphere to the accretion disk, even if a way could be found of maintaining this asymmetry for many orbital cycles so as to produce the light curves. That optical, UV and X-ray radiations all vary in broadly the same manner cannot be consistent with a hot spot model.

This behaviour is exhibited by the AM Herculis stars, and an AM Her model might therefore seem attractive. However, it too can be ruled out. The constant black-body component of the spectrum of TT Ari is distorted by the Balmer jump in emission. Estimating its temperature, therefore, as ~12,000 K from *UBV* colours rather than from its apparent peak emission at 3,000 Å we can then calculate its area (taking $i = 45°$) as $\sim 10^{20}$ cm^2. There is no room for such a large constant black body in the usual model for an AM Her type system.

The observations do, however, fit a DQ Herculis type model with a slowly (synchronously, or almost so) rotating white dwarf. The constant 'black body' is due to an accretion ring rather than a disk. At the inner edge of this ring the accretion is funnelled down the magnetic field of the white dwarf. The accretion spot at the base of the magnetic accretion columns is thought to have two components (see ref. 10): a hot, optically thin region which produces the hard X rays, and below this a photospheric region radiating most of the accretion luminosity with a black-body-like spectrum ($T \sim 3 \times 10^5$ K) which dominates the EUV and the soft X-ray region. If the magnetic field of the white dwarf is offset from the rotation axis the changing aspect of the accretion spot provides a natural explanation for the optical and UV variation. We also note that the absorption lines such as N V, Si V and He II may be formed in the hot photospheric region. More plausibly, any wind flowing from the system may cause these absorption lines.

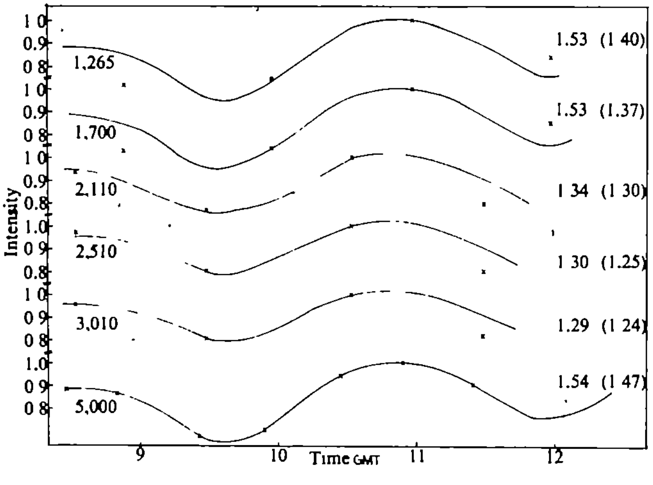

Fig. 2 The 1,265, 1,700, 2,110, 2,510 and 3,010 and 5,000 Å light curves of TT Ari. Fluxes are normalized such that maximum light is unity. The numbers on the right give the amplitudes (maximum/minimum) of the curves and in parentheses the amplitudes derived from the observations alone.

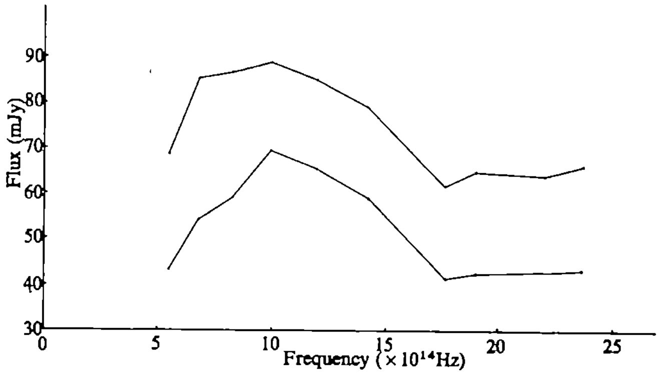

Fig. 3 The maximum and minimum light spectra of TT Ari. 1,360 Å and 1,580 Å have been added.

The sinusoidal modulation of the hard X rays is more difficult to understand as they must come from an optically thin region and there is no evidence for eclipses (we always see just one magnetic pole) or absorption events (K. O. Mason, personal communication). Such sinusoidal modulations are seen in the hard X-ray light curves of some AM Her systems (such as EF Eri = 2A0311 − 227 (ref. 11), where there is also an absorption event, presumably due to the accretion stream crossing the line-of-sight). It is hard to believe that these modulations are caused by electron scattering by material outside the X-ray source: apart from the difficulty of holding the scattering material in place so as to produce regular light variations, any plausible arrangement will also give photoelectric absorption events, contrary to observation. This cannot be overcome by photoionization, since to remove the *K*-shell electrons from the absorbing elements requires[12] $L_x \gg 10^3 N_e r^2$, where L_x is the X-ray luminosity, r the distance from the X-ray source and N_e the average electron density in the scattering material. As the scattering optical depth $\tau_{es} \lesssim N_e r \sigma_T$ must be $\gtrsim 1$ and $r \gtrsim 10^{10}$ cm in any plausible configuration, we require $L_x \gg 10^3 r \tau_{es}/\sigma_T \gg 10^{37}$ erg s^{-1} to get scattering without absorption, considerably in excess of the total luminosity of TT Ari. This would also be a serious problem for a model invoking hard X-ray production in the boundary layer of an accretion disk extending down to the white dwarf surface. A possible explanation for the hard X-ray variation in an accretion spot model comes from the fact that half of the emitted X rays hit the stellar surface: of these some fraction a_x are scattered outwards again. This scattered (albedo) component will be sinusoidally modulated by an aspect effect just like the soft X rays and EUV. Clearly this idea will work best if a purely scattering albedo ($a_x \sim 0.7$) (ref. 13) as opposed to a scattering plus photoelectric absorption albedo ($a_x \sim 0.3$) (ref. 13) is appropriate.

A second difficulty for our model is the shape of the UV continuum, which is much flatter than the Rayleigh–Jeans continuum ($F_\nu \propto \nu^2$) expected from the accretion spot. We note that in AM Her the UV continuum is $F_\nu \sim \nu^{-1}$, although the eclipsed component does have $F_\nu \propto \nu^2$ (ref. 14). X-ray reprocessing is suspected in AM Her, and may be operating here.

Some cyclotron radiation may be expected from material in the accretion columns. However, because the magnetic field must be weaker than in AM Her this is only likely to contribute in the IR. Furthermore, any such radiation will be heavily diluted by the IR tails of the accretion spot, accretion ring and the red star. Neverthless, it would be interesting to look for such weak polarization in the IR. TT Ari is known to be unpolarized in the optical region[15,16].

The variation of the C IV, Mg II emission lines is puzzling as these must, in any model, come from an optically thin region. Radial velocity studies are needed to establish the likely sites of these emission regions. Modulation could arise if they are near the heated inner face of the secondary or the base of the accretion columns. We note that large emission line variations are seen in the magnetic rotator EF Eri[17].

The period of rotation of the white dwarf must be the photometric period, 0.1329 days as given by Smak and Stepien[5]. The binary period is, of course, given by the spectroscopic period of 0.13755 days: it would seem therefore that TT Ari has only recently broken away from the synchronism of an AM Her type system.

One might expect to see a reflection effect, due to the reprocessed UV and X rays, off the secondary. This will be best seen when the secondary is viewed over the white dwarf and the magnetic pole of the white dwarf points towards the secondary. This situation will recur every 3.93 days. Observations of such an effect would test our model and confirm the spectroscopic and photometric periods. We note, however, that the predicted ~4-day period is very sensitive to errors in the photometric and spectroscopic periods. In particular if these periods are closer than current values suggest the 'beat' period may become unobservably long.

We also note that the quasi-periodic variations on time scales of about 14 min (ref. 4) may be related to the free fall time down the accretion columns. This would imply an inner orbital period of the accretion ring of ~56 min. This would be variable as the Alfvén radius varies with the kinetic energy density of the ring which in turn depends on the mass transfer rate.

Clearly, our model describing TT Ari cannot be regarded as certain. Many of the problems, however, are caused by a lack of detailed theoretical understanding of the processes associated with accreting magnetized white dwarfs, for example the X-ray variation problem in a non-eclipsing system such as EF Eri. Equally clear is that a classical hot spot cannot explain the UV and X-ray variation. The axisymmetry of models involving an accretion disk with X rays generated at the white dwarf boundary layer makes it very difficult to modulate the short wavelength UV and X rays, because absorption events are not seen and scattering can be ruled out.

Although we have described TT Ari as a DQ Her type system it is perhaps truer to say it is intermediate between the DQ Her and AM Her types. Indeed, one can see a sequence of objects DQ Her (71), H22521035 (805), TT Ari (11,474) and AM Her (synchronized) where the numbers in parentheses represent the spin period of the white dwarf in seconds. Of course, if the spectroscopic period is in error and does equal the photometric period then TT Ari would be an unusual type of AM Her system in which the magnetic field was weak enough to allow the formation of an accretion ring.

We thank the SERC for providing the opportunity to observe with IUE, and the staff at Vilspa for help, M. Ward for his optical spectrum and K. O. Mason for useful discussions. M.R.S. and J.F. have SERC research associateships.

Limits on a radio shell around the Crab Nebula

A. S. Wilson

It has been suggested[1] that the supernova of AD1054, which produced the Crab Nebula, was of Type II and resulted from the explosion of a massive (10–15 $M_\odot$) star. In this picture, the well known optical filaments represent material which originated predominantly in the core of the star and has been accelerated outwards by the pulsar activity. This nebula is supposed to be surrounded by a faint, massive (~10 $M_\odot$), high velocity (≥5,000 km s^{-1}) shell[2] or halo, which was the envelope of the presupernova star. Such an outer halo may have been recently detected at optical wavelengths[3]. We report here a high sensitivity search at radio wavelengths for the hypothetical outer shell. No shell has been detected and the upper limits indicate that any such shell is fainter than expected from the surface brightness—linear diameter (Σ–D) relation for shell type supernova remnants. Alternative explanations for the optical halo[3] are mentioned.

Observations were made in 1975 and 1976 with the Westerbork Synthesis Radio Telescope[4,5] which then consisted of 12 equatorially mounted paraboloidal antennas distributed over 1.5 km along an east–west line. In searching for a hypothetical radio shell around the Crab Nebula, it is desirable to observe at a low frequency, as the spectrum of the shell is expected to be steeper than that of the pulsar driven nebula, which has $\alpha = 0.26$ ($S \propto \nu^{-\alpha}$) (ref. 6). The frequency used, 610 MHz, provided excellent 'dynamic range' and sensitivity to low brightness features, as well as adequate resolution (55 × 151 arc s, $\alpha \times \delta$, FWHM). As the observations were primarily intended for mapping the weak linear and circular polarization of the nebula, a special observing technique was used[7]. The procedure involved two 12-h observations of the Crab Nebula, one with the two perpendicular linearly polarized dipoles in each telescope at position angles (PA) 0° and 90° and the second with them at PA 45° and 135°. Because of the great brightness of the central nebula, it was necessary to attenuate the signals in the parallel channels on the shorter baselines, to prevent saturation in the correlators. Unnecessary loss of signal-to-noise was, however, avoided by performing greater attenuation on the shorter baselines, in effect 'matching' the sensitivity of the instrument to the visibility curve of the radio source. Each of these 12-h observations was sandwiched between two observations, with the same dipole positions, of the calibration source 3C147 to establish accurately the instrumental polarization and by two observations of the same calibrator with the dipoles in their normal positions[8], to derive the instrumental amplitude and phase corrections. This entire sequence was performed once in March 1975 and again in January 1976, resulting in four independent full (12 h) syntheses of the total intensity distribution. These four maps are in excellent agreement and we use mainly the results of the first series of observations, as the 'dynamic range' is better. Results of the polarization mapping will be presented elsewhere.

At the present resolution the details seen in the highest resolution centimetre wavelength maps[9,10] are smeared out and the cleaned[11] map of the nebula (Fig. 1) shows a smooth, elongated brightness distribution. Averaging the four individual observations, the total flux density is $S_{610\,\mathrm{MHz}} = 1{,}085 \pm 30$ Jy,

0028–0836/82/450155—03$01 00

in good agreement with earlier measurements[6]. The observed major × minor axes of the nebula (with no correction for beam smoothing) are 4.4×3.1 arc min in PA = 152° at 50% of the peak intensity (FWHM) and 10.4×7.6 arc min in PA ≃ 150° at 0.5% of the peak intensity. Assuming a gaussian brightness distribution, the approximate deconvolved[12] sizes are 3.8×2.6 arc min in PA 134° to FWHM, and 8.9×5.6 arc min PA 124° at 0.5%. This deconvolved FWHM is similar to other measurements at centimetre wavelengths[9]. Although the deconvolution is obviously not precise, the size at the 0.5% level may be significantly larger than the total size of 7×5 arc min found at 5 GHz (ref. 9), presumably because of the higher 'dynamic range' of the present data. It is also slightly larger than the optical dimensions of 7×4.8 arc min given by van den Bergh[13]. About 5 arc min to the north of the pulsar, a radio protrusion is seen in the second and third contours. This protrusion lies close to, and slightly to the north of, the optical 'jet-like' feature[13,14]. However, the low resolution in the declination direction renders the position of the radio feature uncertain and higher resolution data are needed to check for a possible association. The extensions to the north seen in the first contour are probably not real.

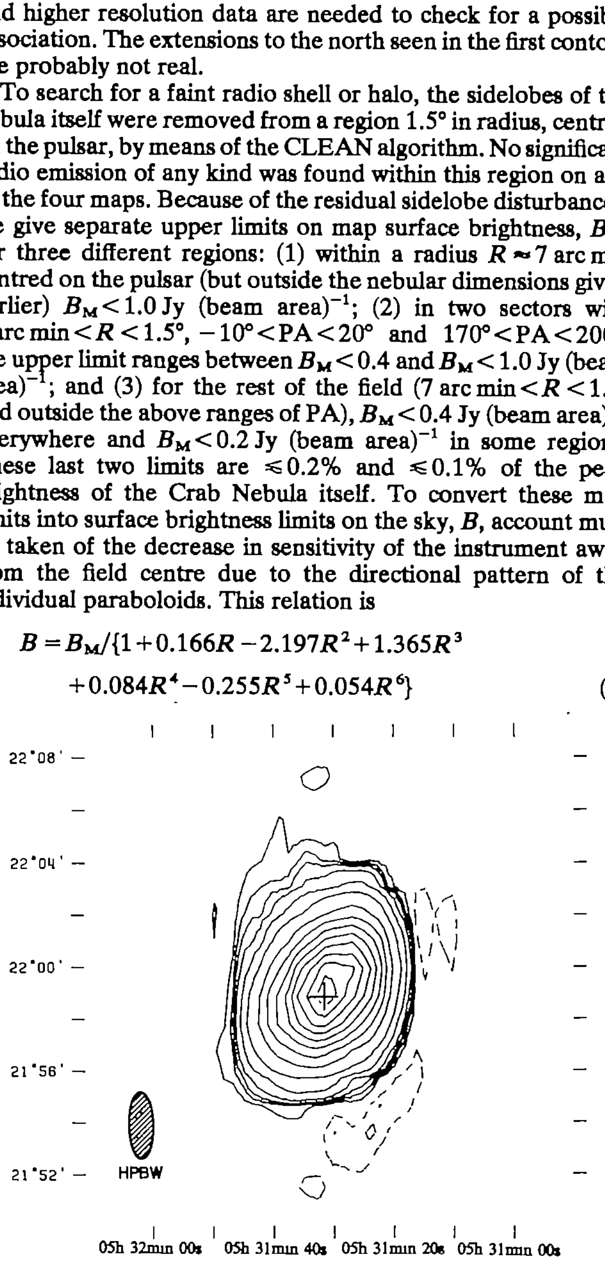

Fig. 1 Contour map of the total intensity distribution in the Crab Nebula at 610 MHz. The beam (55×151 arc s, $\alpha \times \delta$) is shown at the bottom left and the cross marks the pulsar. Contours are plotted at: −2, −1, 1, 2, 3, 5, 10, 20, 40, 60, 80, 100, 120, 140, 160, 180 Jy (beam area)$^{-1}$. Negative contours are dotted lines, positive contours are solid lines.

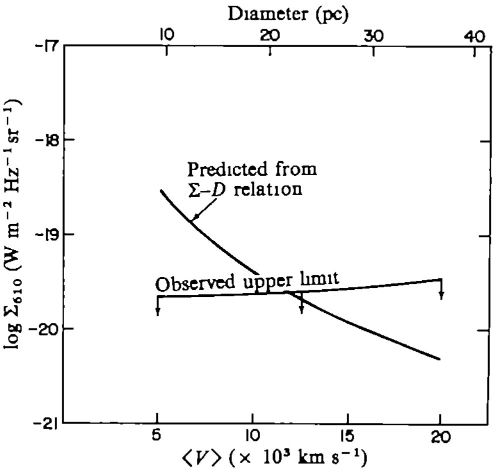

Fig. 2 Plot of surface brightness at 610 MHz (Σ_{610}) against present linear diameter or mean expansion velocity for a hypothetical radio shell around the Crab Nebula at a distance of 2 kpc. The expected mean surface brightness from the Σ–D relation[15] ($|z| = 200$ pc) and the observed upper limit are shown.

To search for a faint radio shell or halo, the sidelobes of the nebula itself were removed from a region 1.5° in radius, centred on the pulsar, by means of the CLEAN algorithm. No significant radio emission of any kind was found within this region on any of the four maps. Because of the residual sidelobe disturbances, we give separate upper limits on map surface brightness, B_M, for three different regions: (1) within a radius $R \approx 7$ arc min centred on the pulsar (but outside the nebular dimensions given earlier) $B_M < 1.0$ Jy (beam area)$^{-1}$; (2) in two sectors with 7 arc min $< R < 1.5°$, $-10° < \mathrm{PA} < 20°$ and $170° < \mathrm{PA} < 200°$, the upper limit ranges between $B_M < 0.4$ and $B_M < 1.0$ Jy (beam area)$^{-1}$; and (3) for the rest of the field (7 arc min $< R < 1.5°$ and outside the above ranges of PA), $B_M < 0.4$ Jy (beam area)$^{-1}$ everywhere and $B_M < 0.2$ Jy (beam area)$^{-1}$ in some regions. These last two limits are $\leq 0.2\%$ and $\leq 0.1\%$ of the peak brightness of the Crab Nebula itself. To convert these map limits into surface brightness limits on the sky, B, account must be taken of the decrease in sensitivity of the instrument away from the field centre due to the directional pattern of the individual paraboloids. This relation is

$$B = B_M/\{1 + 0.166R - 2.197R^2 + 1.365R^3 + 0.084R^4 - 0.255R^5 + 0.054R^6\} \quad (1)$$

where R is the distance from the pulsar ($\alpha(1950.0) =$ 05 h 31 min 31.46 s, $\delta(1950.0) = +21°58'54.8''$) in degrees. Thus the upper limit on B is just twice the upper limit on B_M at 41 arc min from the field centre and is negligibly (7%) larger than B_M at 14 arc min (the maximum radius of the optical halo[3]). These upper limits on B may, in turn, be converted into limits on conventional surface brightness by means of

$$\Sigma_{610}(\mathrm{W\,m^{-2}Hz^{-1}sr^{-1}}) = 5.5 \times 10^{-20} B\,(\mathrm{Jy(beam\ area)^{-1}}) \quad (2)$$

Thus for the typical upper limit of $B < 0.4$ Jy (beam area)$^{-1}$, equation (2) implies $\Sigma_{610} \lesssim 2 \times 10^{-20}$ W m^{-2} Hz^{-1} sr^{-1}.

We may compare our limits with the surface brightness–linear diameter (Σ–D) relation for shell-type supernova remnants. While this relationship is empirical and of weak predictive power, it remains the major yardstick for studying the radio evolution of supernova remnants. Using the form determined by Caswell and Lerche[15] and converting from a surface brightness at 408 MHz to one at 610 MHz, assuming a mean spectral index $\alpha = 0.45$ (ref. 16), gives the relation

$$\Sigma_{610}(\mathrm{W\,m^{-2}\,Hz^{-1}\,sr^{-1}}) = 0.8 \times 10^{-15} D_{pc}^{-3} \exp(-|z_{pc}|/175) \quad (3)$$

where Σ_{610} is the mean surface brightness of the remnant and D_{pc} and z_{pc} are its linear diameter and height above the galactic plane. A shell of radius 14' around the Crab Nebula at a distance of 2 kpc ($D = 16.3$ pc) and a height above the galactic plane of $|z| = 200$ pc (ref. 17) would, therefore, be expected to have a mean surface brightness of $\sim 6 \times 10^{-20}$ W m^{-2} Hz^{-1} sr^{-1} and at least a factor of two higher rim brightness for a typical shell. As this value exceeds our radio brightness limit by $>3\sigma$, it is clear that if the optical halo detected by Murdin and Clark[3] represents the remnant of the supernova of AD1054, it is atypically weak in the radio range.

A more general way of considering this problem is shown in Fig. 2. The observed upper limit to the 610 MHz surface brightness over most of the map area is shown and compared with the empirical mean surface brightness for shell type remnants from equation (3). As any associated shell is presumed to have an age identical to that of the Crab Nebula itself, an average expansion velocity for each shell size can also be calculated for the abscissa in Fig. 2.

As may be seen, the observed limit lies below the mean expected value for all expansion velocities below $\sim 12{,}000$ km s^{-1}. In fact, because most remnants show appreciable limb brightening, the actual surface brightness in the shell itself would be larger than the mean value computed from the Σ–D relation. Thus the radio observations conflict with the predictions for essentially all plausible expansion velocities.

Therefore, we conclude that any hypothetical shell radio source is fainter than expected from the Σ–D relation. We emphasize that a shell like that of SNR1006 (G327.6+14.5) (ref. 18) would have been barely detected by our observations. However, this source is very faint for its diameter, a fact which may be ascribed to its large distance from the galactic plane ($|z| = 340$, 575 or 1,012 pc, depending on whether the distance is derived from ancient historical records[19], from the $\Sigma(D, z)$ relation[15] or from a $\Sigma(D)$ relation[16]), as its properties are not inconsistent with equation (3).

Theoretical treatments of the radio emission from young supernova remnants commonly rely on an interaction between the ejected material and the surrounding interstellar gas to generate the requisite cosmic rays and magnetic fields[20,21]. In Gull's model[20], the radio emission rises to a maximum when the ratio of mass swept up ($= 1.3 < V_{5,000}^3 > n_{0\,1}\, M_\odot$ for the Crab, where $n_{0\,1}$ is the ambient interstellar density in units of $0.1\ \mathrm{cm}^{-3}$) to mass ejected ($\simeq 10\, M_\odot$ in Chevalier's model[1]) is about 0.1. This model suggests, therefore, there should be significant radio emission from the shell at present. Obviously more quantitative models of the evolution of the radio emission from young shell remnants are needed before comparison with our limits becomes meaningful.

Various possible interpretations of the optical halo[3] include: (1) emission from the hypothetical remnant shell; (2) a 'Strömgren sphere' in interstellar gas or in gas lost by the presupernova star, which is ionized by the non-thermal UV synchrotron radiation of the nebula[22]; (3) light scattered off dust grains surrounding the nebula[3]; and (4) leakage of synchrotron emitting electrons from the nebula[23]. The non-spherical shape of the halo[3] may render (2) implausible while any interpretation, such as (3), must be consistent with the apparent absence of excess dust absorption in and surrounding the Crab[24], as well as the halo's emissivity in the band straddling Hα used by Murdin and Clark[3]. The most direct way to prove possibility (1) would be the detection of high velocity gas in the halo through optical spectroscopy; in fact, Henry *et al.*[25] have recently claimed the detection of gas expanding at velocities of 2,300–7,200 km s^{-1}. Further X-ray observations are also desirable to confirm and map a possible soft X-ray 'halo' peripheral to the nebula[26], although this halo is probably the result of scattering of X rays from the central synchrotron source by interstellar dust rather than emission from a hot thermal plasma[27].

A.S.W. was supported by a Royal Society European Program Fellowship (Sterrewacht, Leiden) and an SRC fellowship (Astronomy Centre, University of Sussex). The Westerbork Synthesis Radio Telescope is operated by the Netherlands Foundation for Radio Astronomy (SRZM) with the support of the Netherlands Foundation for Pure Research (ZWO).

Note added in proof: R. B. C. Henry has informed us that the high-velocity emission lines suspected in ref. 25 are of instrumental origin.

Simultaneous radio scattering and white light observations of a coronal transient

Richard Woo & J. W. Armstrong

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91109, USA

N. R. Sheeley Jr, R. A. Howard, D. J. Michels & M. J. Koomen

E.O. Hulbert Center for Space Research, Naval Research Laboratory, Washington DC 20375, USA

Comprehensive observations of coronal transients have been made using the OSO 7 (ref. 1), Skylab[2–4], Solar Maximum Mission[5] and currently Solwind[6,7] coronographs. An important question in regard to understanding these transients and their relationship to solar radio burst observations[8] and *in situ* solar wind measurements[9] is whether the shock front produced by the disturbances corresponds to the white light front. It has recently been demonstrated[10] that spectral broadening measurements of monochromatic spacecraft radio signals represent a useful tool for detecting and studying shocks near the Sun. We now report that a coronal transient observed by the Solwind coronograph off the west limb of the Sun on 24 October 1979 was also seen in the spectral broadening observations of the Helios-2 2.3-GHz radio signal. A comparison of these simultaneous data suggests that in this case the shock front does not coincide with the white-light front but in fact precedes it.

Figure 1 shows four coronal images obtained with the Solwind instrument[6] on 24 October, 1979. The upper images were taken at 0316 and 1258 UT while the lower ones are difference images formed by subtracting the images at 0536 and 0804 UT from that at 0316 UT to show the changes that had taken place in the coronal intensity. The west limb brightening is always present during 0316–0804 UT, but a small loop transient does occur during 0536–0804 UT. The Helios-2 raypath, which is in the ecliptic plane off the west limb of the Sun, moves towards the Sun at the rate of 25 km s^{-1}. 'X' in the 0536–0316 UT difference image marks the location of the Helios-2 raypath at 0536 UT. As can be seen, the Helios-2 raypath is well positioned to observe the transient whose front progressed in an almost westward direction.

Although the front of the moving coronal material is not precisely defined, its speed can be estimated and appears to be very slow. The heliocentric distances of the coronal front at 0536 and 0804 UT are $4.5 \pm 0.5 R_\odot$ and $6.0 \pm 1.0 R_\odot$ respectively, yielding an outward speed (in the plane of the sky) of ~ 120 km s^{-1}. However, because of the uncertainties in location, the range of speeds is 0–240 km s^{-1}. Height–time profiles for both the Helios-2 raypath and the white light coronal front measurements are summarized in Fig. 2.

Figure 3 shows the time history of the spectral broadening bandwidth BW of the Helios-2 2.3-GHz signal on 24 October 1979 during 0200–1400 UT. Values of BW, the full width between frequencies enclosing half the area underneath the RF spectrum[10,11], were computed using an integration time of 2 min. The increase in BW depicted in Fig. 3 exceeds that which would be expected due to the systematic increase in background corona towards the Sun[11]. The BW profile in Fig. 3 is similar in shape to that for a shock wave observed by Voyager 1 on 18 August 1979 (Fig. 2*a* in ref. 10), and although we cannot be certain, the similarity in shape indicates that the event in Fig. 3 is also probably a shock wave. Of course, it is clear from the differences in BW variation and time scale that the Helios-observed shock is substantially less intense and slower than the

0028–0836/82/450157—03$01.00

Voyager-observed shock. The pre-shock bandwidth of 5 Hz at 2.3 GHz is in agreement with the measurements of the background solar corona near $5R_\odot$ (ref. 11).

Bandwidth increases are caused by enhancements in turbulence (electron density fluctuations) or acceleration of the solar wind[11] and can be separated by analysing the amplitude scintillations if they are weak[10]. Unfortunately, the Helios measurements took place near $5R_\odot$, where the 2.3-GHz amplitude scintillations are saturated and strong[12] so that detailed profiles of the wind speed and turbulence cannot readily be obtained as was done in the case of the Voyager measurements[10]. The first region of enhanced bandwidth in Fig. 3 (0500–0700 UT) corresponds to the shock front and the compressed turbulent region behind it, while the second broad but lower enhanced region (0700–1400 UT) following the first is probably the turbulent wake.

Based on the coronal transient speed of 120 km s^{-1} determined from the Solwind pictures, the white light coronal front would have crossed the Helios-2 raypath at $5.2R_\odot$ around 0700 UT, which is 2 h after the shock arrival time of 0500 UT (see Fig. 3). Alternatively, the 0536–0316 UT difference image in Fig. 1 shows that the white light coronal transient had not reached the Helios raypath at 0536 UT whereas the shock had already been detected 36 min earlier in the Helios radio tracking data. The cross-hatched region in Fig. 2 corresponds to the times at which the white-light front would have crossed the Helios raypath when the range of heliocentric distances at 0536 and 0804 UT is considered. As can be seen, the delay in white light coronal front arrival is at least 1 h for all possibilities. This result is consistent with the fact that path-integrated electron density as determined from radio measurements of phase in the case of the 18 August shock peaks well behind the shock front[10].

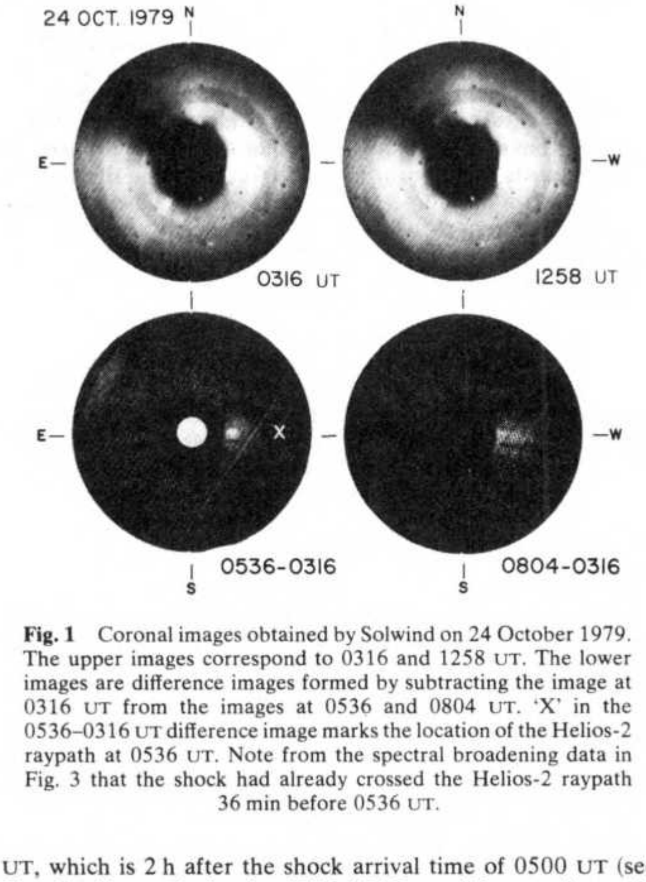

Fig. 1 Coronal images obtained by Solwind on 24 October 1979. The upper images correspond to 0316 and 1258 UT. The lower images are difference images formed by subtracting the image at 0316 UT from the images at 0536 and 0804 UT. 'X' in the 0536–0316 UT difference image marks the location of the Helios-2 raypath at 0536 UT. Note from the spectral broadening data in Fig. 3 that the shock had already crossed the Helios-2 raypath 36 min before 0536 UT.

Let us estimate the shock speed. Assuming that the white light coronal transient has a constant speed of 120 km s^{-1}, the start time at the Sun's surface would have been 2358 UT on 23 October. As discussed earlier, the shock crossed the Helios raypath at about 0500 UT and according to Fig. 2 the heliocentric distance was $5.5R_\odot$. If we assume that the shock originated from the Sun's surface at the same time as the white-light front and travelled at a constant speed to $5.5R_\odot$, we obtain a shock speed of 170 km s^{-1}. The ambient solar wind speed is about 80 km s^{-1} (ref. 12), so the Helios-observed shock must be rather weak. This result is consistent with the fact that the bandwidth increase is substantially smaller for the Helios than for the Voyager-observed shock. It is interesting that the shock speed calculated on the basis of transit time for the Voyager shock was 2,300 km s^{-1} (ref. 13), which is a factor of 13.5 higher than that of the Helios shock. This is approximately the same factor relating the time scales of the bandwidth time histories of the Voyager and Helios shocks. The consistency of the Helios and Voyager spectral broadening observations in this regard reinforces the notion that the event observed by Helios is indeed a shock.

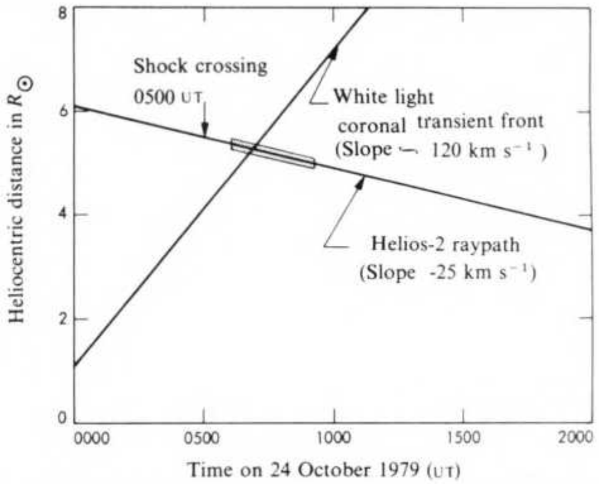

Fig. 2 Height–time profiles for the Helios-2 raypath and Solwind white light coronal front measurements. The cross-hatched region indicates the possible range of intersections between the Helios-2 raypath and the white light transient front allowing for the 120 ± 120 km s^{-1} uncertainty in the measured transient speed.

Because of the paucity of radio scattering measurements using spacecraft radio signals, there have been few opportunities to compare simultaneous radio scattering and white light measurements of coronal transients. The results presented here are based on only one relatively weak coronal transient but clearly show that the shock front is ahead of the white light front. Additional observations of larger events, particularly when solar radio noise burst and *in situ* spacecraft observations are conducted at the same time, will contribute significantly to our understanding of coronal transients and their evolution as they propagate away from the Sun.

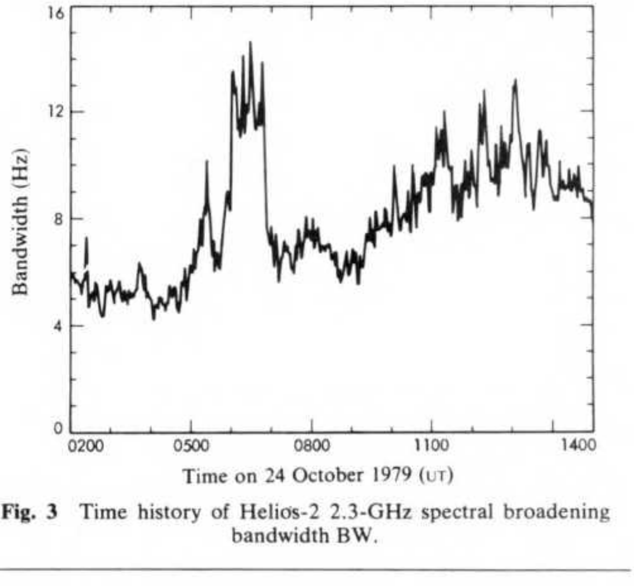

Fig. 3 Time history of Helios-2 2.3-GHz spectral broadening bandwidth BW.

Aquatic chemistry of plutonium in seasonally anoxic lake waters

Edward R. Sholkovitz, Anne E. Carey & J. Kirk Cochran

Department of Chemistry, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

We present here data on the distribution of the fallout radionuclides ^{55}Fe, ^{239,240}Pu, ^{137}Cs and ^{90}Sr and the natural radionuclides ^{238}U and ^{234}U in a seasonally anoxic lake in an effort to determine their biogeochemical behaviour. Results from Gull Pond, Massachusetts show that the oxygen-depleted and iron- and manganese-rich bottom waters contain five times more dissolved ^{239,240}Pu than oxygenated surface waters. This feature, also observed in anoxic hypolimnia of other lakes, indicates that the concentration of plutonium is significantly influenced by anoxicity and redox cycles. Such observations are important in understanding the fate of artificial radionuclides which are released[1–4] to the aquatic environment through global fallout, planned disposal and localized accidents.

The oxidation–reduction chemistries of iron and manganese are important in aquatic systems because they can directly or indirectly control the concentration, distribution and speciation of inorganic and organic constituents[5–7]. In many temperate lakes the development of thermal stratification in summer causes the hypolimnion to become depleted or devoid of dissolved oxygen[5,8–14]. In such conditions, reductive dissolution of sedimentary Fe(III) and Mn(IV) oxides occurs, releasing dissolved Fe(II) and Mn(II) to the overlying water[5,8–14]. Anoxic hypolimnia can have large concentrations of dissolved Fe(II) and Mn(II). Ferrous iron is then rapidly oxidized in the oxygenated part of the water column to form suspended particles of Fe(III) oxides[5–15].

Many natural radionuclides (such as uranium, thorium, radium, ^{210}Pb, ^{210}Po) and artificial radionuclides (such as plutonium, americium) are known to be strongly adsorbed onto the oxyhydroxides of iron and manganese[16,17]. Therefore, the reductive dissolution and oxidative precipitation of iron and manganese oxides in seasonally anoxic lakes may result in changes in the aqueous concentration of several radionuclides. For plutonium and uranium with their multiple oxidation states[18–25], variations in redox conditions may lead to changes in speciation and hence concentrations in lake waters.

Gull Pond, a small (0.5 km^2) kettle hole lake in Wellfleet, Cape Cod, Massachusetts, develops an anoxic hypolimnion during the late summer (Fig. 1). On 19 August 1981, we collected a vertical profile of water from the deepest basinal part of the lake (22 m depth). Large volume water samples for radiochemical analyses were obtained by pumping water from depth up a plastic hose, through an AMC Cuno Micro-Wynd II filter cartridge with a nominal 1 μm pore size and into 60-1 LPE Deldrums. Water samples were filtered without contact with the atmosphere. Such handling is necessary with anoxic waters to prevent the rapid oxidation of dissolved Fe(II) iron to particulate Fe(III) oxide particles. If this reaction did occur before filtration, then the Fe(III) oxides thus formed would probably scavenge dissolved nuclides resulting in the measured dissolved and particulate nuclide concentrations being too low and too high respectively.

Dissolved (<1 μm) radionuclides, iron and manganese were measured on the 2, 15 and 20 m samples. Using Niskin bottles, a series of smaller samples were collected for analysis of dissolved O_2 and total iron and manganese. Oxygen was measured by the Winkler titration and iron and manganese by flame atomic absorption spectrometry. The radiochemical analyses were performed according to published methods—^{239,240}Pu (ref. 45), U (ref. 46), ^{55}Fe (refs 26, 27), and ^{137}Cs (ref. 28) and ^{90}Sr (ref. 28).

The seasonal anoxicity of the hypolimnion in Gull Pond has been described elsewhere[29]. During our August sampling (Fig. 1) there was a large decrease with depth in the concentration of dissolved oxygen in the thermocline (9–16 m); and an anoxic hypolimnion existed between 16 m and the bottom (22 m). The oxygen decrease was accompanied by large increases with depth in the concentrations of total iron and manganese. These two elements were predominantly in the dissolved form (<1 μm; Table 1). The iron and manganese gradients are typical of those observed in other seasonally anoxic lakes[5,10–12,14].

The concentration of dissolved ^{239,240}Pu has a 4.6-fold increase between 2 and 20 m with the larger gradient occuring in the anoxic hypolimnion between 15 and 20 m. The gradient for plutonium is much greater than those of dissolved ^{137}Cs, ^{90}Sr and U (Fig. 1). The plutonium profile is more similar to that of ^{55}Fe which has a steep gradient and follows that of stable iron. Iron-55 (half life of 2.7 yr) was introduced with plutonium in the global fallout from atmospheric nuclear explosions testing[30]. The data from Gull Pond show that dissolved ^{239,240}Pu concentrations are higher in the anoxic hypolimnion. The relative amounts of plutonium in the dissolved and particulate phases have not been measured. Release from the sediments to the water column in anoxic conditions is suggested by the similarities in the plutonium and ^{55}Fe gradients.

The only published studies of plutonium distributions in anoxic lakes are those of Experimental Lake 241, a meromictic Canadian lake with permanently anoxic bottom water[31–33] and Par Pond (S. C.), a lake with a seasonally anoxic hypolimnion[34]. In ELA-241 the dissolved ^{239,240}Pu concentration increases from 6 to 10 fCi l^{-1} between 0 and 9 m, then increases to 48 fCi l^{-1} at 11 m (Fig. 2). The bottom water has high (but unspecified) concentrations of dissolved iron and manganese and displays a large increase in conductivity[31–33]. Wahlgren *et al.*[32,33] have determined that ~80% of the dissolved ^{239,240}Pu in ELA-241 is in the reduced (III+IV) state.

Four vertical profiles (Fig. 2) of ^{239,240}Pu in Par Pond reveal variations which may be linked to redox cycling. The profile in February 1976 shows no vertical gradient when the lake is well mixed. Profiles in July 1975 and August 1976 show the deepest samples up to 20 times more concentrated in plutonium than those in the overlying water. Albert and Orlandini[34] reject their

‡ ^{55}Fe data decay corrected to date of collection (19 August 1981).

high bottom water concentrations of dissolved plutonium in July 1975 as an artefact, do not discuss the high bottom value in total plutonium in the August 1976 profile, and conclude that plutonium is not involved in the redox cycles of iron and manganese.

The results of both studies are ambiguous in that they are not accompanied by basic data indicative of the redox reactions occurring in the lakes at the time of sampling (for example, dissolved O_2, particulate and dissolved iron and manganese). Moreover, it is not clear what precautions were taken to prevent oxidation of dissolved ferrous iron before filtration.

We conclude that the Gull Pond data presented here, supported by the ELA-241 and Par Pond results, indicate that significantly higher dissolved plutonium concentrations are found in anoxic lake waters than in overlying oxic waters. We suggest that the plutonium gradients result from the release of plutonium to water column from the sediments during periods of anoxicity. The exact geochemical processes remain to be established; the possibilities include: (1) plutonium, adsorbed onto sedimentary oxides of iron and/or manganese, is released to the water column as the oxides are reductively solubilized in anoxic conditions[17,34]; and (2) redox transformations lead to a more soluble oxidation state of plutonium possibly through the formation of organic-Pu(IV) complexes (D. M. Nelson, personal communication); chemical modelling[24,25] suggests that in anoxic conditions in lakes the concentration of plutonium will increase due to the higher solubility of Pu(III) in equilibrium with $Pu_2(CO_3)_3$.

The concentrations of ^{137}Cs, ^{90}Sr, ^{234}U and ^{238}U increase only slightly (1.3–1.6-fold) with depth from the surface to the hypolimnetic sample. In comparison with the Great Lakes[35–38], the Gull Pond waters have similar concentrations of dissolved ^{90}Sr but are greatly elevated in ^{137}Cs. The ratios of $^{137}Cs/^{90}Sr$ in Gull Pond range from 0.71 to 0.79. This ratio is approxi-

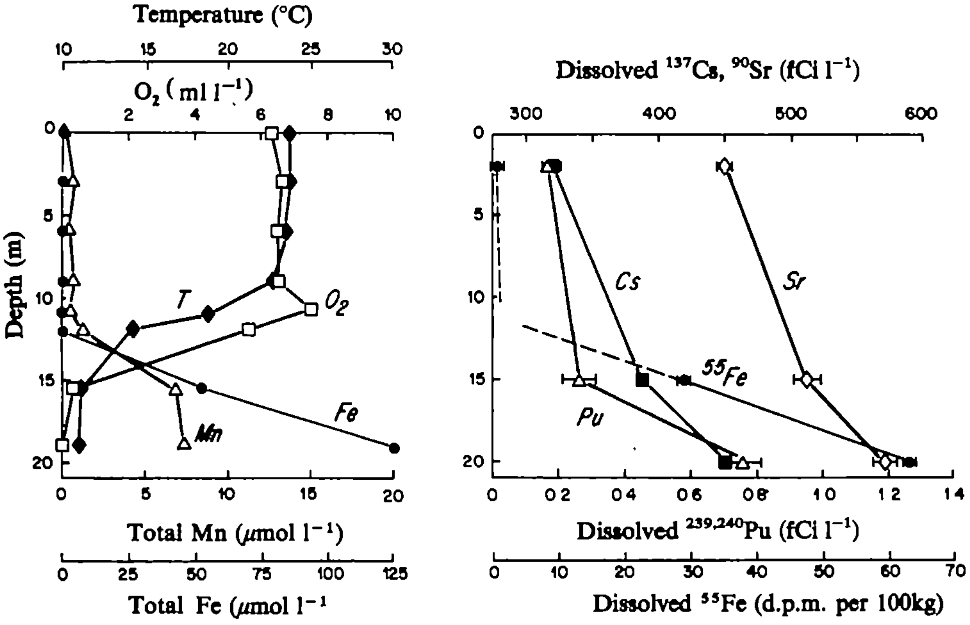

Fig. 1 Chemical composition of the water column in Gull Pond on 19 August 1981. The dashed lines for ^{55}Fe, which intersect at 12 m, are based on the more complete profile of stable Fe. Dissolved refers to constituents passing through a Micro-Wynd Cartridge filter with a nominal pore size retention of 1 μm. Water depth at the sampling location was 22 m.

mately half that of global fallout[39] (1.6 ± 0.2) and 5–20 times greater than ratios measured in the Great Lakes[36,37]). The low clay and high sand content of the soils and lake sediments of Cape Cod may lead to diminished exchange capacities and less uptake of dissolved ^{137}Cs from lake and ground waters.

For Gull Pond the water column (0–20 m) inventories of ^{137}Cs and ^{90}Sr are 8 and 10 mCi km^{-2}. These represent about 7 and 12% of the fallout delivery at this latitude. The water column ^{239,240}Pu inventory is 3.5×10^{-3} mCi km^{-2}, only 0.4% of the fallout delivery. These inventory values are calculated for the deepest part of the lake where our samples were taken and thus are upper limits. They indicate that a major fraction of the fallout nuclides are not in the water column.

The different vertical gradients of ^{137}Cs, ^{90}Sr and U relative to Pu and ^{55}Fe imply that there may be different geochemical and/or hydrological processes operating on these groups of radionuclides. It can be argued that the slightly increasing concentrations in Cs, Sr and U may be due to multiple water sources to the pond, redox controlled release from sediments, or biological removal in the surface water and release at depth. In lakes like Gull Pond, which are predominantly ground water fed, the influence of ground water hydrology on the water column chemistry may be an important unknown[40].

There is some evidence from other anoxic lakes that the Fe/Mn redox cycle may be responsible for increases in the hypolimnetic concentrations of ^{137}Cs (refs 41, 42) and ^{90}Sr (ref. 47). U concentrations are thermodynamically predicted and observed to be very low in anoxic groundwaters[18,19]. However, in anoxic marine sediments, U pore water concentrations are elevated over those of oxygenated seawater[42–44]. The formation of more soluble complexes of U(IV) with organic matter and/or carbonate may be responsible. Because U can exist in several oxidation states and form complexes, it is not unreasonable to expect it to be involved in redox and biogeochemical cycles. This is not usually considered to be the case for Cs and Sr. However, a recent study[5] of a seasonally anoxic lake shows that cations such as K, Mg, Ca and Ba are indirectly involved in the redox cycles. More geochemical and radiochemical data from seasonally anoxic lakes will elucidate the magnitude of fluxes between sediments and overlying water, the extent of post-depositional remobilization and redistribution, and the interaction between suspended particles and the water.

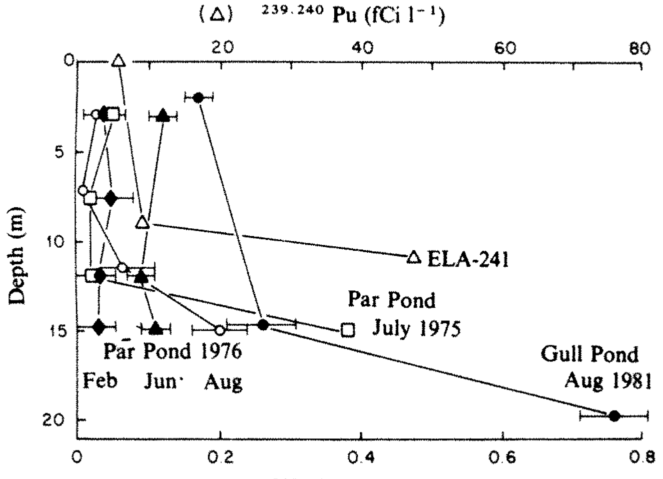

Fig. 2 Profiles of dissolved ^{239,240}Pu in lakes with anoxic hypolimnia. See text for discussion. Water samples from Par Pond (Cold Dam), ELA-241 and Gull Pond were filtered through 0.45, 0.22 and 1.0 μm, nominal sized filters respectively; the only exception is the August 1976 data from Par Pond which are for unfiltered water samples. The maximum water depths are respectively about 16, 12 and 22 m.

We thank J. C. Burke, S. A. Casso, L. B. Clarke, W. R. Clarke, C. H. Clifford, L. Goodell, A. G. Gordon and D. S. Schneider for assistance with boat handling, sample collection and radiochemical analysis; and the authorities of Wellfleet, for allowing us to sample their pond. Research was supported under contract AC02-81EV10694 from the US Department of Energy to Dr Vaughan T. Bowen and by the University of Edinburgh to E.R.S. This is contribution no. 5123 from the Woods Hole Oceanographic Institution.

Preferential elution of strong acids from a Norwegian ice cap

T. D. Davies, C. E. Vincent & P. Brimblecombe

School of Environmental Sciences, University of East Anglia,
Norwich NR4 7TJ, UK

The release of strong acids by melting snows during the early thaw has a serious effect on the ecology of many sensitive areas of the world[1–3]. The run off is a product of both the input (wet and dry deposition) and of processes occurring within the snowpack and the firn during the melt season. Temperate glacial ice is very pure[4], having lost most of its annual input of original solutes during each melt season, and the analyses reported here of the ionic concentrations in the snow, firn and ice of the top 20 m of an ice cap, indicate that the ions are eluted differentially and in a manner which initially accentuates the loss of sulphuric and nitric acid. Almost all the annual deposits of ions on a glacier or ice cap may be lost during a single year.

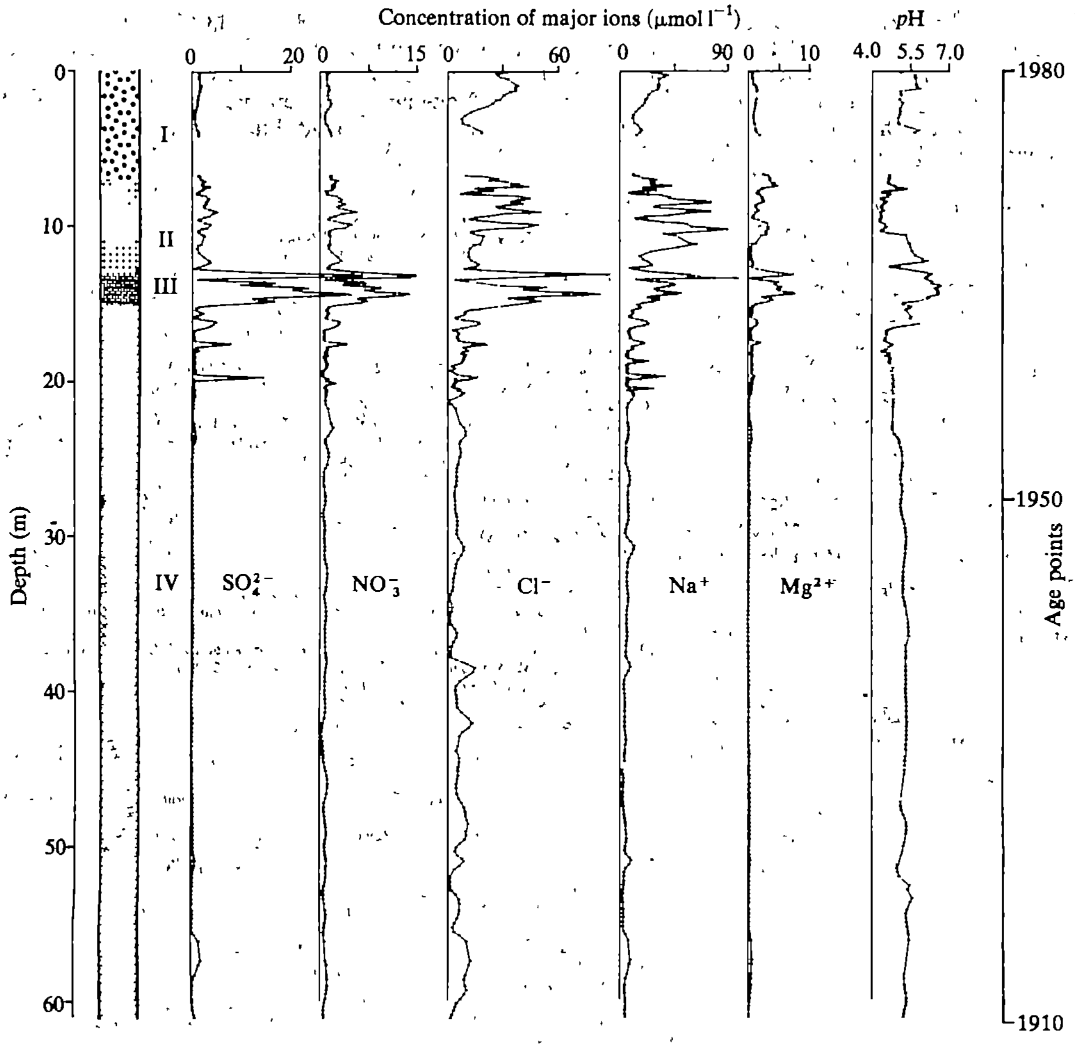

Fig. 1 Distribution of major ions down the ice core; the data have been smoothed using a 5-point binomial filter. Structure of core: I, snow and firn; II, firn and open-structured ice; III, ice with vertically-connected bubble system; IV, bubbly ice. The age points are based on climatically-reconstructed accumulations, simple flow models and tritium determinations.

An ice core, 61 m long, was recovered from the secondary summit (1,625 m ASL) of the Folgefonni Ice Cap (60°04′ N, 06°23′ E) near Bergen, Norway at the end of July 1980. The annual net accumulation at the drilling site is about 1 m water equivalent. Precipitation would be 3–4 times this amount and have approximate inorganic ion concentrations of: sodium, 100; chloride, 115; nitrate, 22; sulphate, 24; magnesium, 10; hydrogen; 35; ammonium, 15; calcium, 8 μmol l^{-1} (ref. 5). The core was retrieved using a hand auger for the upper snow and firn and a portable thermal corer[6] for the more consolidated firn and ice. The core was returned to the UK in its frozen state for analysis. About 1 m of core between 6 and 7 m was lost during the transfer from hand auger to thermal corer. The overall structure of the core was: 0–7 m snow and firn, 7–13 m firn and relatively open-structured ice, 13–15 m a zone of ice with systems of vertically interconnected bubbles, below 15 m bubbly ice (Fig. 1). The retrieved core (7-cm diameter) was cut into disks (5-cm thick). Before analysis, an outer 1-cm annulus was removed and the remaining central sections sluiced with deionized water until about half of the original volume remained. The firn sections were cut using carefully cleaned polytetrafluoroethylene (PTFE) tools and not washed with deionized water. All samples were filtered through 0.22-μm nucleopore filters. The anionic components were determined on a Dionex 12 ion chromatograph. Concentrations of the sulphate and nitrate anion were determined to better than 10% accuracy in the 1–10 μmol l^{-1} range with a detection limit of 0.1 μmol l^{-1}. Chloride levels were determined to 10% accuracy with a 0.5-μmol l^{-1} detection limit. Sodium and magnesium were determined on a Pye Unicam SP9 atomic absorption spectrometer; accuracy was ~5% and detection limits better than 0.5 μmol l^{-1}. The H^+ ion concentration was determined with a pH meter read to 0.1 pH unit. The ionic composition of the core below 20 m was more constant relative to the upper 20 m and analyses were made only on every fifth disk.

The distribution of major ions down the core is shown in Fig. 1. The few NH_4^+, Ca^{2+} and K^+ determinations available (the small volume of the ice disks precluded complete ion analysis) indicate that these ions probably provide the necessary charge for balance. The concentration of ions in the ice below 20 m are generally an order of magnitude lower than that which would be expected from the composition of the precipitation input. This is in agreement with earlier observations[7,8]. More striking is the high peak in concentrations at 12–15 m, where the ice had many vertically interconnected bubbles. The peak is most pronounced for nitrate and sulphate. Below the water table (20 m) the concentration of ions is very low, which suggests that the bulk of the inorganic solutes are removed from the ice cap. Summing the ions present above this point yields approximately: SO_4^{2-}, 0.070; NO_3^-, 0.050; Cl^-, 0.40; Na^+, 0.46; Mg^{2+}, 0.030 mol m^{-2}. These values are of the same order as a single year's input of inorganic ions for such an area of southwestern Norway, indicating that much of the ion input since the 1979 melt season had not yet (at the time of core retrieval) been removed from the ice cap, although it has been redistributed through deeper (and older) ice. The melt water percolates down through the upper open-structured layers of the ice cap each year, taking the bulk of the ionic components of that year's input with it. These reach the water table and are ultimately lost from the ice cap, eventually leaving residual concentrations of the level in the lowest 40 m of the core.

However, the percolation does not occur without redistribution among the ions. The ratios of the volume-averaged concentrations of ions in the top 3 m of the core, C_{0-3} (representing the remaining winter input), to the average ionic concentrations in the entire top 20 m of the core, C_{0-20} are: SO_4^{2-}, 0.39; NO_3^-, 0.58; Cl^-, 1.20; Na^+, 0.90; Mg^{2+}, 1.15. These values may be seen as some kind of retention index (a proportion of the ions, particularly the more mobile ones, may already have left the system and this will distort the calculated values), and suggest that some ions are eluted from the snow and firn more rapidly than others. Differential enrichment of the ions is also apparent in the vertically ducted ice zone (C_{12-15}/C_{0-20}): SO_4^{2-}, 3.8; NO_3^-, 2.5; Cl^-, 1.9; Na^+, 1.4; Mg^{2+}, 3.5. Our examination of data from snowpack studies[8-10] show similar rankings in terms of ion retention, with Cl^- and Na^+ being retained longer, NO_3^- retained for shorter periods and SO_4^{2-} and Mg^{2+} being the most mobile of the measured ions. Thus, the fractionation process (removal of the bulk of the impurities from the snowpack in the first fractions of meltwater) that has received much comment[7-10], is also a differential process, releasing some ions more quickly than others.

The average ion concentrations of various sections of the ice core are shown in Fig. 2. Note that Na^+ and Cl^- seem to be less mobile than the NO_3^- and SO_4^{2-} in the ice column. Our examination of snowpack data[8-10] also indicates the high mobility of the H^+ ions which probably therefore accompany the mobile NO_3^- and SO_4^{2-} ions as a strong acid peak appearing relatively early in the melt season. A hint of this process may be seen at the 12–15-m peak, where the SO_4^{2-} and NO_3^- concentrations are high, and the removal of each SO_4^{2-} and NO_3^- ion would lead to the associated removal of three H^+ ions. The H^+ concentration is low in this part of the core and the charge is balanced by NH_4^+ and K^+ (which, on the basis of the measurements made so far, appear to be relatively immobile). The C_{0-3}/C_{-20} value for H^+ is 0.48, confirming the high mobility of the ion, but the distribution of H^+ down the ice core does indicate the complexity of the removal process, and the effects of buffering might conceal even larger H^+ ion mobilities. If a melting season was reasonably long then we would expect the more slowly removed Na^+ and Cl^- ions to appear after the acids, making the total removal of ions equal to the input, maintaining a steady-state condition. However, short melting seasons might allow temporary retention of the less mobile constituents. The fractionation has previously been observed in snowpacks, but here we can see it occurring in a vertically extended ice core in a differential manner. It does allow us to perceive the way in which the 'acid flush' may arise from an ice cap, a situation which has some similarities with snow melt and is of obvious importance to the vernal acidification of watercourses.

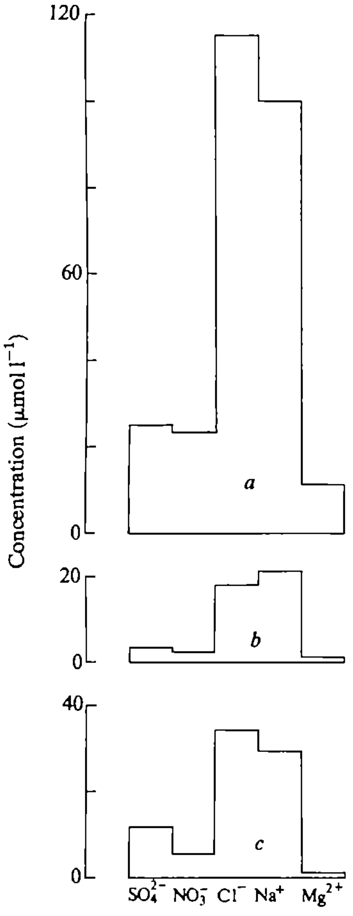

Fig. 2 *a*, Composition of precipitation input on the glacier since 1979 melt season, estimated from Norwegian Institute for Air Research data *b*, Average composition of 0–20 m zone of ice core. *c*, Average composition of 12–15 m zone of ice core.

The recovery of the ice core and part of the laboratory analyses were funded by the Central Electricity Generating Board. We thank Dr G. Østrem, K. Boge, Professor Y. Gjessing, Drs B. Fisher, T. Manning, M. Mitchell for help and cooperation, Frank Robinson for work on the thermal corer and him and Keith Bostrom for sampling assistance, and Jo Vincent and Sotiris Tsouris for analytical assistance.

Department of Geology and Geophysics, Woods Hole
Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

The discovery of a marked isochronous decrease of carbon isotope ratio values (~0.5–0.8 ‰ in marine carbonates at about 6.2 Myr has stimulated several speculations regarding the origin of this event[1-3]. Here we report stable isotope studies of planktonic and benthic foraminifera from the late Miocene Carmona–Dos Hermanos section in southwestern Spain which suggest that (1) the carbon shift at 6.2 Myr is directly associated with a eustatic sea-level lowering recorded in the same section; (2) the shift in $\delta^{13}C$ at 6.2 Myr and other times may be related to an increased flux of marine and terrigenous organic matter depleted in ^{13}C and eroded from the continental shelves during sea-level lowstands; and (3) the sea-level fall at 6.2 Myr triggered the rapid shift towards hypersaline conditions in the Mediterranean well before the deposition of the Messinian evaporites.

.Climatic and oceanographic events that may be closely associated in time with the decrease in $\delta^{13}C$ values include: (1) an overall cooling of surface water[4,5]; (2) an increase in bottom

water circulation rates and fertility of the oceans[2]; (3) lowering of sea level[6,7]; (4) the isolation and drying up of the Mediterranean[8,9]; (5) the shoaling of the Isthmus of Panama[10], (6) an increase in biogenic silica removal in the Southern Ocean high productivity zone[11]; (7) a decrease in biogenic silica sedimentation in the eastern equatorial Pacific[12]; (8) a change over from an Atlantic carbonate compensation depth (CCD) shallower than the Pacific CCD before the shift to a deeper CCD in the Atlantic after the shift[13]; and (9) an increase in deep-sea accumulation rates[14]. The cause of the decrease in $\delta^{13}C$ values and its apparent close temporal association with these other palaeoceanograpic phenomena has not been established.

One way to decrease oceanic $\delta^{13}C$ values is to introduce isotopically light (−20 to −25‰) organic matter to the open ocean by eroding it from the continental shelves during a sea-level lowstand[2,15]. A eustatic lowering of sea level has been reported close to the time of the carbon shift[6,9,16]. However, because the carbon shift has mostly been reported from deep-sea drilled sections and eustatic sea-level lowerings are documented in shallow land-based marine sections, direct correlation has proved difficult. Our stable isotopic study of marine carbonates from a land-based marine section in southwestern Spain reveals an abrupt $\delta^{13}C$ shift which coincides with a previously recorded latest Miocene sea-level fall[6].

The Guadalquivir Basin in southwestern Spain (Fig. 1) appears to represent a fully marine equivalent of the Messinian evaporite sequence[6]. Its position in the Betic Straits region in southern Spain which acted as a gateway controlling water movements between the Atlantic Ocean and the Mediterranean Sea during the Miocene[8] and its shallow depth make it ideal for studying the relationship between sea-level events, climatic changes and Messinian events in the western Mediterranean region.

The Carmona–Dos Hermanos section consists of three units (Fig. 2). The lower 'blue marls' or 'marne azzure' are a thick sequence of marls containing abundant planktonic and some benthic foraminifera and are overlain by a band of alternating sands and marls—'sandy marls'[6]. The upper unit known as the Caliza Tosca is a coarse-grained limestone containing abundant molluscan shell fragments and a high percentage of quartz.

Berggren and Haq[6] examined the distribution of benthic foraminiferal assemblages in the Carmona section and estimated changes in bathymetry based on comparisons with the depth distribution of similar living assemblages. Below the Caliza Tosca the benthic foraminiferal fauna is relatively homogeneous, but between samples C9 and C12 (Fig. 2) there is a sequential elimination of certain species. Between samples C10 and C13 benthic foraminifera species diversity drops from 46 to 3 species. The dramatic benthic faunal changes at this location, between samples C9 and C13, have been interpreted to reflect a local sea-level fall of ~200 m due to the combined influence of long term uplift in the Betic region and more rapid global causes[6].

Carbon isotopic ratios in both planktonic and benthic foraminifera decreased dramatically by nearly 1‰ between samples C10 and C12, reflecting a change in seawater isotopic

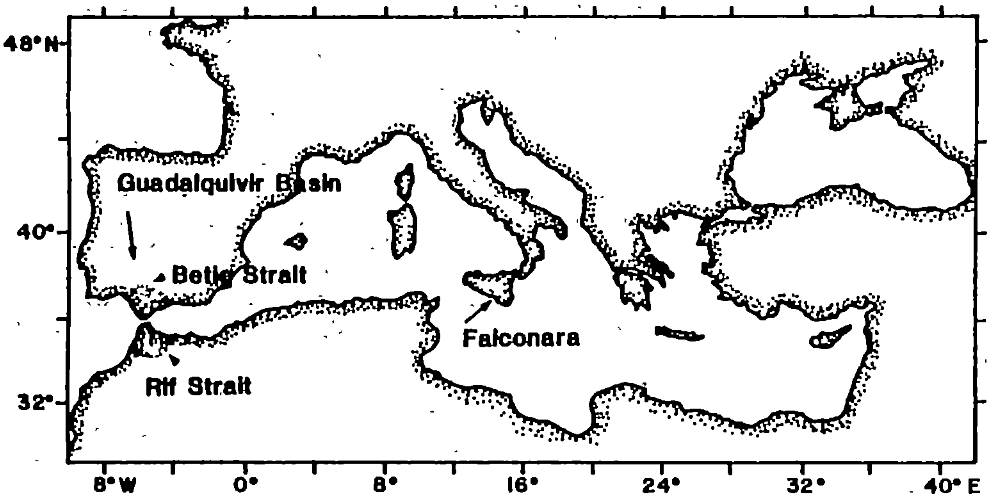

Fig. 1 Map of the Mediterranean Sea and surrounds showing the location of features referred to in the text (modified after ref. 30).

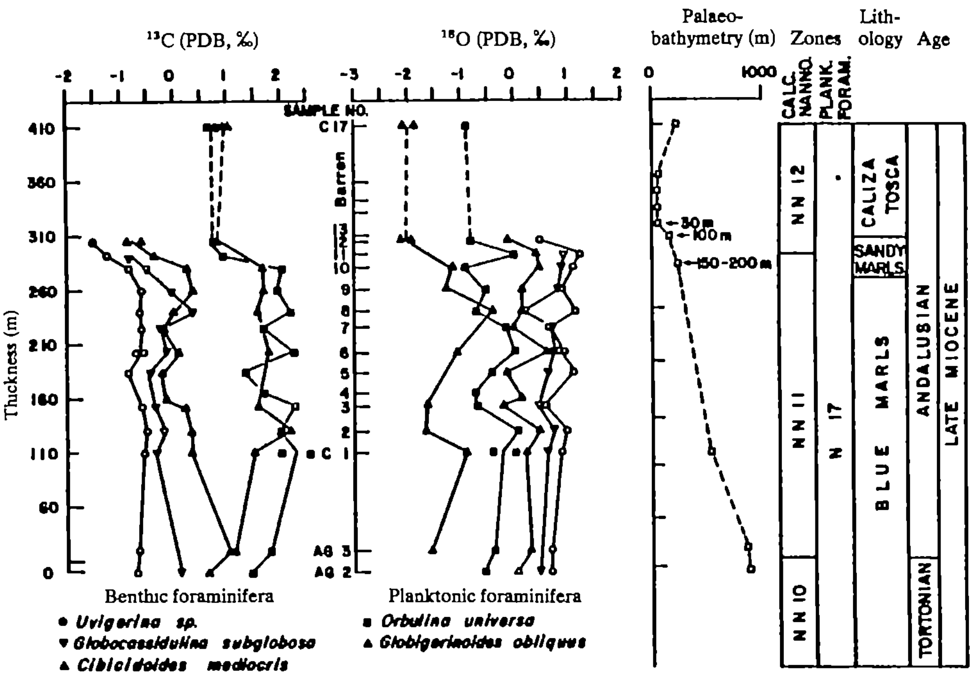

Fig. 2 Benthic and planktonic oxygen and carbon stable isotopic results (‰, PDB), palaeodepth estimates[6] and microfossil zonation schemes and lithology[6] from the late Miocene Carmona–Dos Hermanos section in southwestern Spain. Two planktonic foraminiferal species, *Orbulina universa* and *Globigerinoides obliquus* and three benthic foraminiferal species, *Uvigerina* sp., *Globocassidulina subglobosa* and *Cibicidoides mediocris*, were picked from the 250–350 μm size fraction and analysed according to standard procedures[17]. Results are presented in the notation

$$\delta‰ = [(R_{\text{sample}}/R_{\text{reference}}) - 1] \times 10^3$$

where $R = {}^{13}C/{}^{12}C$ or ${}^{18}O/{}^{16}O$, respectively, for $\delta^{13}C$ or $\delta^{18}O$ with respect to PDB (see ref. 17).

composition (Fig. 2, Table 1). An estimate of the timing of the $\delta^{13}C$ shift in the Carmona section is critical to understanding its origin. Is it related to the latest Miocene carbon isotopic shift reported[2,3,17] in the Indian, Pacific and Atlantic Oceans? Based on the Berggren and Haq study[6] the carbon shift recorded in the Carmona section appears to occur within the lower part of the Messinian between 6.5 and 5.5 Myr. It is difficult to define the age of the $\delta^{13}C$ decrease at this location because the stratigraphical position of each biostratigraphical datum is poorly defined (±15 m) due to wide sample spacing and the reliability of each datum when applied in the Mediterranean region is questionable. The placement of the Caliza Tosca as being coeval with the Mediterranean evaporites is based on stratigraphical position and the absence of *Discoaster quinqueramus* from one sample (C12) rather than on positive evidence and is therefore also questionable[9]. The widespread Epoch 6 marker *Amaurolithus primus* found below the carbon shift in many Pacific sections is not present in the Carmona section.

The latest Miocene open ocean carbon shift is dated palaeomagnetically at ~6.2 Myr within magnetic chron 6 [6,18,20]. On the basis of biostratigraphical criteria, we cannot state that the carbon isotopic shift in the Carmona section is time-equivalent with the open ocean shift. On the other hand, the similarity in age of the isotope shifts, the fact that the shifts occur in both planktonic and benthic foraminifera simultaneously and that the magnitude of the shifts is similar, suggest that a globally synchronous geochemical event which affected both shallow and deep ocean waters is also recorded in the Mediterranean region.

Oxygen isotope results at the Carmona section reveal that the magnitude of the average difference between values from the benthic foraminifera *Uvigerina* and the shallow dwelling planktonic foraminifera *Globigerinoides obliquus* is nearly constant and >2‰ (Table 1, Fig. 2). This isotopic difference probably reflects a surface to bottom temperature contrast of 8–9 °C because the benthic foraminifera fauna (*Bulimina*, *Discorbis*, *Cibicides* and *Melonis*) suggest normal marine rather than hypersaline conditions. Also the presence of psychrospheric ostracods in the middle to late Miocene Mediterranean Sea indicate cool bottom water temperatures[21]. Similar planktonic and benthic foraminiferal $\delta^{18}O$ differences are found elsewhere in the Mediterranean[22].

One possible way of rapidly decreasing organic $\delta^{13}C$ values in the latest Miocene is by introducing oxidized organic matter or increasing the rate of flux of carbon from a major carbon reservoir to the ocean[2,15]. Such changes could be produced by increasing the oxidation of organic matter on the deep ocean sediment surface as a result of increased benthic erosion and higher oxygen content in deep waters[1,3]. However, Broecker[15] has suggested that the cycle of production, deposition and removal of continental shelf sediments during transgressions and regressions across the shelf could produce a significant change in open ocean $\delta^{13}C$ values. The shelves act as a sink for carbon during transgressions and a source during regressions, when erosion supplies previously deposited organic matter, depleted in ^{13}C, to the open ocean[2,15].

Close temporal association of the distinct global negative carbon isotopic shift and a eustatic lowering of sea level in the latest Miocene suggest that the two may be causally linked. In addition the correspondence between sea-level changes and a negative $\delta^{13}C$ shift in marine carbonates recorded at Carmona has been noted in two New Zealand land sections: Blind River and Eketahuna[18]. Many late Miocene sections record significant lowerings of sea level evidenced by a global lack of shallow water carbonates, facies changes in ostracod faunas and benthic foraminifera[9] and marine phosphorite deposits[23]. Palaeontological correlation of such events is especially difficult because of the removal of continental margin sequences by erosion, the short-time interval involved and poor micropalaeontological control in many continental margin sequences. The sea-level fall is estimated to have been between 70 and 100 m and to have occurred rapidly ($<10^4$ yr). Such rapid changes in sea level are inferred to have been caused by glacio-eustatic events. Based on oxygen isotopic analyses of marine carbonate in DSDP Site 284, Shackleton and Kennett[24] suggested that an increase in Antartic ice-volume sufficient to produce a sea-level fall between 40 and 70 m occurred in the latest Miocene. However, further isotopic analysis of many late Miocene DSDP drill sites and piston cores have found $\delta^{18}O$ changes similar in magnitude to that recorded at Site 284 throughout the late Miocene, but no permanent change in oxygen isotopic values[17,25,26]. This apparent incompatibility between stratigraphical, lithological and oxygen isotopic evidence for a latest Miocene sea-level change hinders a full understanding of late Miocene palaeoceanography. We suggest two possible mechanisms for this incompatibility: (1) the oxygen isotopic record is missing during the critical time due to unconformities and (2) large amounts of continental ice, more enriched in ^{18}O than Antarctic ice, were formed in the latest Miocene. Evidence for the first mechanism is provided by detailed biostratigraphical studies which reveal a hiatus in nearly all latest Miocene sediment recovered from the Pacific Ocean by the Deep Sea Drilling Project[27]. The second mechanism is supported by Mercer and Sutter[28] who suggest that a Northern Hemisphere ice-sheet about one-half the size of the Pleistocene Laurentide ice-sheet formed in the latest Miocene. The formation of this ice-sheet with an isotopic composition of ~ -30‰ could significantly lower sea level without dramatically raising the $\delta^{18}O$ of the oceans.

An understanding of the structure of the water column in the Betic area before the eustatic lowering of sea level and the Messinian evaporitic events allows us to place constraints on the stratigraphical position of the Caliza Tosca. Studies by Cita *et al.*[29] and Hsü *et al.*[30] indicate that the changes from open marine conditions occurred suddenly ($<10^4$ yr). There is no evidence in the Carmona section for a rapid increase in salinity to hypersaline conditions before the sea level fall. There is, however, a small (<0.5‰) gradual increase in bottom water $\delta^{18}O$ values up the section which possibly occurred as a result of the slow tectonic uplift of the Betic straits region gradually restricting bottom water return flow to the Atlantic. Thus, a eustatic lowering of sea level cut off the return flow to the Atlantic of deep waters resulting in rapid isolation of the Mediterranean Sea and causing hypersaline conditions.

We tentatively correlate the rapid lowering of sea level at Carmona with the beginning of hypersaline conditions within the Mediterranean region. A change to hypersaline conditions in the deep waters of the Mediterranean would have occurred rapidly as a result of surface water evaporation once the bottom water return flow to the Atlantic was shut off in the Betic straits. Initially, a restricted supply of North Atlantic surface waters maintained normal marine surface water salinities in the Mediterranean but eventually as the Atlantic portal closed the surface waters also became hypersaline. Total evaporation could have occurred within $\sim 10^3$ yr of final closure of the Atlantic–Mediterranean gateways. Thus, the change to hypersaline conditions in the Mediterranean probably occurred within at most, a few thousand years, of the eustatic sea-level event recorded at Carmona and therefore provides a valuable stratigraphical marker within the Mediterrean region independent of biostratigraphical criteria. Hypersaline conditions are recorded in the Tripoli (marly diatomites) of the Falconara section in Sicily[31,32], situated very near the Messinian stratotype sections at Pasquasia and Capodarso. Planktonic foraminiferal[31] and bulk carbonate[32] $\delta^{18}O$ values increase dramatically in the upper part of the Falconara section at the base of the Tripoli formation immediately following the demise of most benthic forminifera, which suggests that the bottom waters became hypersaline before the surface waters.

We suggest that a eustatic sea-level fall recorded at Carmona and the global decrease in $\delta^{13}C$ values correlate with the lowermost Tripoli Formation based on the almost simultaneous (within 5,000 yr?) change to hypersaline conditions in the Falconara section. If we are correct in assigning an age of 6.2 Myr to the sea-level event and associated carbon isotope shift then the base of the Tripoli in the Falconara section is ~6.2 Myr. If the absence of *Nitzschia miocenica* and *Thalassiosira praeconvexa* is due to ecological exclusion[33], then the Tripoli could be as old as magnetic chron 6, in good agreement with our age estimate.

Isotopic and geochemical studies of nodules in kimberlite have implications for the lower continental crust

M. T. McCulloch*, R. J. Arculus*, B. W. Chappell† & J. Ferguson‡

Australia

Lower crustal xenoliths from the Calcutteroo kimberlitic pipes in South Australia show a surprisingly diverse range in Nd and Sr isotopic compositions and rare earth element (REE) abundances. Mafic granulite and garnet–clinopyroxenite xenoliths have measured $\varepsilon_{Nd}(0)$ values between +6.1 and −7.9, both light (L)REE enrichments and depletions, low Rb/Sr ratios (0.005–0.040) and relatively high $^{87}Sr/^{86}Sr$ ratios of from 0.70675 to 0.70919. A felsic xenolith has compositions more typical of upper crustal rocks with $\varepsilon_{Nd}(0) = -21.4$, LREE enrichments, Rb/Sr = 1.47 and $^{87}Sr/^{86}Sr = 0.85987$. An approximate correlation also exists between Sm/Nd versus $^{143}Nd/^{144}Nd$ and Rb/Sr versus $^{87}Sr/^{86}Sr$ indicating major intracrustal differentiation in the lower crust at ~2,400 Myr. This produced extremely low Rb/Sr ratios, and both relative LREE enrichments (low Sm/Nd) and depletions (high Sm/Nd). If these results are typical, then they indicate that the lower crust has higher $^{87}Sr/^{86}Sr$ and more positive $\varepsilon_{Nd}(0)$ values than previous estimates[1–5]. This may require revision of total crustal compositions and crust–mantle evolutionary models[1–5].

Although the composition of the upper continental crust is established reasonably well by direct observations, the composition of the lower crust remains uncertain. Xenoliths derived from lower crustal depths by kimberlite magmas provide one of the few direct means of sampling the lower crust, as it exists *in situ* at present. In this study, we present Nd and Sr isotopic data, together with selected trace element abundances for lower crustal xenoliths from the Calcutteroo kimberlitic pipes in South Australia. The kimberlite host rocks of the inclusions are intruded into folded, Proterozoic marine sediments[6], located in the Flinders Range, about 230 km north of Adelaide in South Australia. Measured Rb/Sr ages on phlogopites separated from kimberlitic matrices are in the range 164–174 Myr (ref. 7).

The inclusions consist of garnet clinopyroxenites, garnet granulites and felsic garnetiferous gneisses. Grain sizes vary

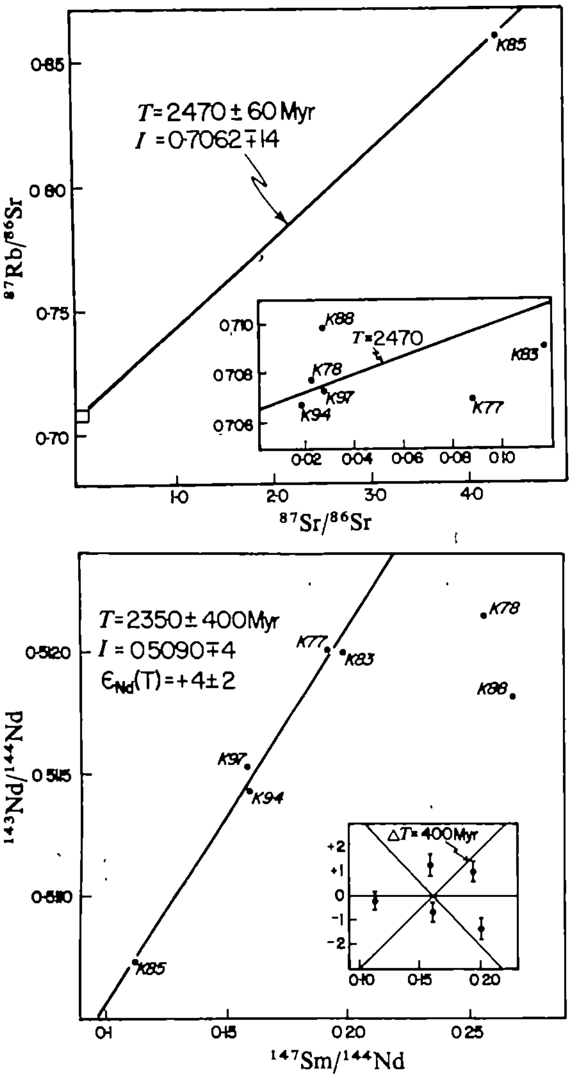

Fig. 1 *a*, Rb–Sr isochron diagram for lower crustal xenoliths from south Australia. The age is controlled by the felsic granulite K85. The low Rb/Sr samples (shown in inset) have significant deviations from the 2,470 Myr isochron but all indicate high initial $^{87}Sr/^{86}Sr$. *b*, Sm–Nd isochron diagram. A regression (excluding K78, K88) gives a similar age to Rb–Sr. Inset shows deviations from the best fit isochron in parts per 10^4. The deviant samples K78 and K88 indicate that the lower crust sampled by the kimberlite is heterogeneous in age and/or initial ratios.

from fairly uniform, microgranular (<0.5 mm) through subequant granular (0.5–1.5 mm) to porphyroblastic (<5.0 mm garnet). Some samples have a distinct mineral lineation. Phase assemblages in the basic inclusions are dominated by omphacitic diopside–salite, intermediate Mg/Fe garnet with ~20–25 mol % grossular, and plagioclase in the compositional range oligoclase–andesine (R.J.A., J.F. and B.W.C., in preparation). Minor and accessory phases consist of rutile, biotite, hastingsitic amphibole, K-rich feldspar, scapolite, quartz, apatite and sphene. The more felsic nodules have a diverse mineralogy including, in the sample analysed for Nd and Sr isotopes, almandine-rich garnet, K-rich feldspar (Ca:Na:K = 0.5:19:80.5), kyanite, quartz, rutile and biotite (Mg/Mg+ΣFe ≈ 0.62). Orthopyroxene, amphibole, sphene, scapolite and rare REE-U-rich phosphate phases are present in variable proportions in other inclusions of intermediate to felsic composition in the Calcutteroo kimberlitic pipes[8] (R.J.A. *et al.*, in preparation). Equilibration temperatures and pressures[9–12] for the inclusions are in the range 800–900 °C, 8–12 kbar equivalent to depths in the crust of the order 25–40 km. The depth of the Moho in this region is suggested to be ~35 km (ref. 13). Most inclusions are basaltic in chemistry with <51% SiO_2, and MgO in the range 7–11 wt%. Intermediate SiO_2 (~55%) and high-SiO_2 (60–68%) inclusions constitute a minor fraction of the inclusion population.

The Sm–Nd and Rb–Sr isotopic measurements are given in Table 1 and shown in Fig. 1*a*, *b*. There are correlations between measured Sm/Nd versus $^{143}Nd/^{144}Nd$ and Rb/Sr versus $^{87}Sr/^{86}Sr$ ratios (Fig. 1*a*, *b*). A regression of all the Rb–Sr isotopic data yields an age of 2,470±60 Myr and an initial $^{87}Sr/^{86}Sr$ ratio of 0.7062±14. The age is controlled solely by the high Rb/Sr sample (K85) and the initial $^{87}Sr/^{86}Sr$ by the remaining low Rb/Sr samples. A regression of the Sm–Nd isotopic data (excluding K78 and K88) yields a similar, although less precise, age of 2,350±400 Myr and an initial $^{143}Nd/^{144}Nd$ ratio of 0.5090±4 (corresponding to $\varepsilon_{Nd}(T) = +4\pm2$). The xenoliths K78 and K88 deviate markedly from this array. These latter samples also have pronounced LREE depletions (Fig. 2) thus excluding the possibility that their REE abundances and Nd isotopic compositions have been modified by contamination with the host kimberlite magma, which is strongly enriched in LREE[8]. Instead, the deviations must reflect some real heterogeneities in age and/or initial ratios of the lower crust sampled by the xenoliths.

The initial $^{87}Sr/^{86}Sr$ ratio of 0.7062±14 is substantially greater than mantle values indicating that the major chemical fractionation event registered by both isotopic systems occurred within the crust rather than as a consequence of mantle–crust differentiation processes. The high initial Sr ratio can be accounted for by a period before ~2,400 Myr of high Rb/Sr ratios within the lower crustal protoliths. For example, with an Rb/Sr ratio the same as K85 (Rb/Sr = 1.5), $^{87}Sr/^{86}Sr$ would evolve in an interval of ~80 Myr from a mantle value of 0.702 to the observed initial ratio of 0.7062. For a Rb/Sr ratio more typical of the upper crust (Rb/Sr = 0.3)[14], this interval would be increased to ~400 Myr. The initial Nd isotopic composition of $\varepsilon_{Nd}(T) = +4\pm2$ indicates derivation from a source which has had a previous history of relative LREE depletion. Although this is generally more characteristic of mantle sources[3,4,15,16], it is still compatible with a relatively short crustal residence time. For example, assuming that the initial crust was LREE enriched (similar to K85), a crustal prehistory of ~100 Myr would reduce the $\varepsilon_{Nd}(T)$ value by ~1 unit. Therefore, to account for the observed ε_{Nd} (2,400 Myr) value of +4±2, this would imply derivation from a mantle source with ε_{Nd} (2,500 Myr) = +5±2, which is still compatible with available constraints[16]. Substantially longer crustal prehistories are possible if the lower crustal protoliths had either chondritic LREE or depleted LREE abundances. This is conceivable considering the highly variable REE abundances in the xenoliths.

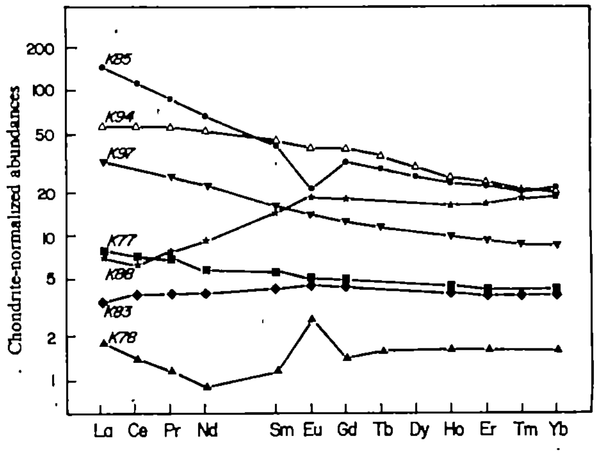

Fig. 2 REE patterns determined using spark-source mass spectrometry[24] and normalized to chondritic abundances. The lower crustal xenoliths have a diversity of patterns and only K78 has the positive Eu anomaly predicted for the lower crust[14,17] and found in the Lesotho granulite xenoliths[25].

‡ $\varepsilon_{Nd}(0)=\left[\frac{(^{143}\text{Nd}/^{144}\text{Nd})}{(^{143}\text{Nd}/^{144}\text{Nd})_{\text{CHUR}}}\text{, sample }-1\right]\times 10^4$, where $(^{143}\text{Nd}/^{144}\text{Nd})_{\text{CHUR}}=0.511836$.

§ Average values calculated by weighing xenoliths according to their relative abundance.

Intracrustal melting at ~2,500 Myr has also been proposed by Taylor[17] and Taylor and McLennan[14] to account for the negative Eu anomaly observed in post-Archaean sediments. During this intracrustal melting event, it is envisaged that the melt becomes enriched in LREE and Rb, and depleted in Eu and Sr as a result of the preferential incorporation of Eu^{2+} and Sr^{2+} into residual plagioclase. Although this mechanism accounts for the low Rb and high Sr abundances, of the xenoliths, only one has a positive Eu anomaly. (In fact, K85 has a negative Eu anomaly.) Thus, at least for the samples analysed in this study, it would appear that retention of plagioclase in the lower crust has not been the major factor controlling the REE abundances. Variations in the abundance of REE enriched accessory minerals (such as allanite, zircon and apatite) could substantially influence the REE abundances in the lower crust, and perhaps compensate for the positive Eu anomaly produced by plagioclase.

The present-day Nd and Sr isotopic compositions are shown in Fig. 3, together with estimates of lower crustal compositions by other workers[1–3,5,14]. The xenoliths analysed in this study clearly differ from all other lower crustal estimates, primarily due to the high measured ^{87}Sr/^{86}Sr ratios and more positive $\varepsilon_{Nd}(0)$ values. Several workers have assumed that the relative REE abundances are the same in both the upper and lower crust[1,2,4,18]. This assumption is based on the observation that Archaean felsic granulites usually have LREE-enriched patterns similar to upper crustal patterns[18–21]. Apart from the *ad hoc* assumption that Archaean felsic granulites are representative of the present day lower crust, the significance assigned to the felsic gneisses ignores the presence in many Archaean granulite terrains (such as Scourian[5,20]) of granulites having intermediate, basic and ultramafic compositions. These latter rock types are all lower in absolute concentration of LREE, occasionally LREE-depleted, and have small positive or negative Eu anomalies. The relative proportions of these more basic rock types in these terrains is conjectural at present, but this study, as well as others on suites from kimberlitic pipes in New South Wales, Victoria, and the Colorado Plateau, USA, all suggest that basic rock types may be an important constituent of the lower crust[8,22,23].

Although reliable estimates of lower crustal compositions must await more data of the type reported here, it is, nevertheless, informative to speculate on its implications for total crustal compositions. Typical upper crust (for a mean age of 1,500 Myr)[1] has $\varepsilon_{Nd}(0) = -15$ and ^{87}Sr/^{86}Sr = 0.7220, Nd = 26 p.p.m. and Sr = 350 p.p.m. (ref. 14). Thus, total crust consisting of 1 part upper crust to 2 parts lower crust[14] has $\varepsilon_{Nd}(0) = -8.3$, ^{87}Sr/^{86}Sr = 0.7173 (for a mean age of 1,500 Myr)[1] and Nd = 16 p.p.m. and Sr = 230 p.p.m. (based on our analyses of lower crustal xenoliths). These compositions are significantly different from previous estimates for the total crust and may require

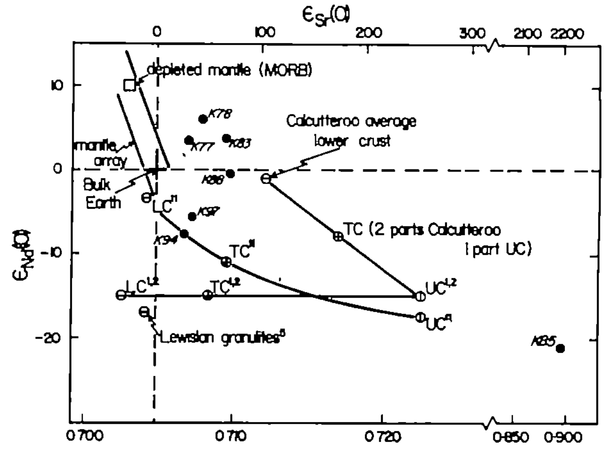

Fig. 3 Present-day Nd and Sr isotopic composition for south Australian lower crustal xenoliths (●). The xenoliths have both positive and negative $\varepsilon_{Nd}(0)$ values and have relatively radiogenic ^{87}Sr/^{86}Sr ratios. The felsic granulite K85 which has extremely high ^{87}Sr/^{86}Sr and negative $\varepsilon_{Nd}(0)$ values is a rare xenolith type. The south Australian lower crustal average is significantly different from existing models particularly those that assume that the relative LREE abundances are the same in the upper and lower crust[1–5,18]. The closest agreement is with the models of Taylor[17] and Taylor and McLennan[14] which assume intracrustal fractionation of Sm/Nd as well as Rb/Sr and thus predict more positive $\varepsilon_{Nd}(0)$ values for the lower crust compared with the upper crust. Lines connecting lower crust (LC ⊖), total crust (TC ⊕) and upper crust (UC ⏀) are calculated by assuming that the lower crust constitutes two-thirds of the total. The inferred total crust composition calculated using the lower crustal xenoliths is also substantially different from previous estimates[1,2,14]. If this is not due to Ha sampling bias, it may imply, for example, the existence of additional reservoirs to satisfy the bulk Earth constraint[1–5] of $\varepsilon_{Sr}(0) = \varepsilon_{Nd}(0) = 0$.

revision of the parameters and assumptions on which some crust–mantle evolutionary models[1–5] are based. In particular, the assumption that the total crust and depleted mantle are strictly complementary and are together equivalent to the bulk Earth[1–5] is not consistent with these results.

We thank S. R. Taylor and W. Compston for provision of analytical facilities and H. D. Hensel, D. Nelson and P. Oswald-Sealy for technical support. D. Windrim and the reviewers provided helpful comments. This project was supported by ARGC grant no. E79.15566 to B.W.C.

Ages and implications of East Pacific Rise sulphide deposits at 21°N

Claude Lalou & Evelyne Brichet

Centre des Faibles Radioactivités, Laboratoire mixte CNRS-CEA,
91190 Gif-sur-Yvette, France

Massive sulphide deposits described as inactive hydrothermal deposits (samples CYP) along the axis of East Pacific Rise (EPR) were first discovered at 21°N, about 700 m west of the active rift[1]. This discovery was followed by that of active vents made of sulphides (samples *Alvin*) in the central part of the rift valley[2]. Due to the importance of the flux of elements presently discharging and its impact on the chemistry of the ocean, it is important to understand the duration of the phenomenon and its possible periodicity. We present here an attempt to date the fossil and the active chimneys using radioisotope methods.

In the oceanic environment, chemical fractionations exist due to differences in geochemical behaviour of the different nuclides forming the decay series of uranium and thorium. Their existence in the hydrothermal environment can be postulated.

(1) The chemical separation between uranium and thorium is well known in normal oceanic conditions, and ^{230}Th has been widely used as a chronometer for oceanic events[3–7]. This method is applicable in the range of some thousands of years to about 300,000 yr. This time span cannot be used for the active vents but may be of interest for the fossil chimneys as the age of the crust on which they lie, at 700 m from the active axis, may be estimated taking into account a mean half expansion rate of 3 cm yr^{-1} (ref. 8) as $\sim$20,000 yr (ref. 1).

Uranium and thorium isotopes have been measured by α- ray spectrometry after chemical separation; results are given in Table 1. To ascertain that no ^{230}Th enters in the sulphides at the moment of the precipitation, on 10 samples from active vents, we have checked that ^{230}Th is always under the detection limit of the apparatus (Table 2), as well as ^{232}Th, so the latter may be used to detect an eventual contamination during alteration.

On two samples from the fossil deposits, CYP 78–08–14 and CYP 78–12–40, we have analysed 11 different subsamples, 8 of them are pure sulphides, they do not contain any ^{232}Th and their ^{230}Th/^{234}U ages are from <2,700 to 6,400 yr (ref. 9), (Table 1). Three subsamples which are partly oxidized exhibit measurable concentrations of ^{232}Th and higher uranium contents. The calculated ages for these samples are 6,900, 18,000 and 36,500 yr. Although the first two do not disagree with the possible age of the basement, we discard them as being wrong due to their probable alteration. Thus, we conclude that a former period of active hydrothermal discharge took place $\sim$4,000 yr ago.

(2) The half life of ^{230}Th, 75,200 yr, precludes its use for dating the chimneys sampled during *Alvin* dives in the central part of the rift valley, so we tried to use different short-lived decay products of the uranium and thorium series.

Turekian *et al.*[10] have used, for the measurement of growth rates of giant clams from Galapagos rise, the ratios ^{228}Th/^{228}Ra; ^{228}Ra/^{226}Ra and ^{210}Pb/^{226}Ra. Those nuclides have half lives between 1,622 and 1.90 yr which seem suitable for our study, provided we know the ratios at the origin of the system. Moreover, we also tried to use the decrease of activity of ^{210}Pb ($t_{1/2}$ = 22 yr), referred to stable lead.

The activities of these nuclides have been measured by non-destructive γ-ray spectrometry, and lead was measured by atomic absorption spectrophotometry.

^{230}Th/^{234}U ages have not been calculated as they have no significance. The error on γ measurements of ^{210}Pb is 10 statistical errors on counting rate + an error on the efficacy of Ge–Li detector estimated as 10%. The error on atomic absorption measurement of Pb is ~5% and has been neglected.

the same origin and the same ^{210}Pb activity at the time of deposition. On nine samples, ^{210}Pb activities were large enough to allow relatively precise measurements even by γ-ray spectrometry, giving ^{210}Pb/Pb ratios from 0.87±0.25 to 0.27±0.03 (Table 2)[12].

In ambient seawater, some Pb and ^{210}Pb may exist, 1 ng per kg (ref. 13) and 20 d.p.m. per 100 kg (ref. 11) respectively; this oceanic component might change the initial ^{210}Pb/Pb ratio and also progressively contaminate the sulphides after their formation. We therefore verified that, in one of the 'old' samples (CYP78-12-40B) containing stable lead, ^{210}Pb activity was below the limit of our method (28±21 d.p.m. g^{-1}) and that on a presently forming sulphide deposit containing almost no Pb (982 chimney), ^{210}Pb is not measurable. So, unless the initial ^{210}Pb/Pb ratio measured by Finkel *et al.*[11] varies from one vent to another in the same field, or if it is different in the sulphides deposited at the vent from the initial one, which is unlikely, the ages so obtained are true ages.

Unfortunately, the samples coming from different vents were not sufficiently documented especially as regards their orientation and position in the walls of the vents, to allow the meaning of the differences in ages to be dicusssed. Either they form continuously and our values are mean values between an older part and a very recent one, and, in this case, it is a lower limit for the beginning of the event, or the chimneys took only a brief time to build and do not grow at present, and our age is the age of the beginning of the event. During the last *Cyatherm* cruise, the instantaneous growth of a chimney has been visualized (R. Hekinian, personal communication) which suggests that our second hypothesis is more valid.

^{228}Th/^{228}Ra method may be applied to samples containing radium. As they do not contain any thorium when they formed, then any measurable ^{228}Th must have formed as a decay product of ^{228}Ra. Due to the relatively short half lives of the two nuclides, the equilibrium value of the activity ratio, 1.4, is obtained after about 15 yr. During this time, ^{228}Ra being unsupported decreases with its half life of 5.75 yr while ^{228}Th increases with its half life of 1.9 yr.

Only two of our samples exhibited ^{228}Th and ^{228}Ra activities measurable by γ-ray spectrometry (Table 3) for which the equilibrium value of the ratio is obtained, giving for the two samples ages >15 yr, which is in accordance with the 46±5 and 54±4 yr found with ^{210}Pb.

The last suitable ratio is ^{228}Ra/^{226}Ra. In such a young system, ^{226}Ra may be considered as stable while ^{228}Ra decreases. The problem is then to know exactly the initial value of the ratio. We may hypothesize that the two nuclides are in equilibrium with their parents ^{238}U and ^{232}Th respectively in the basalt and that they are not differentiated during leaching and precipitation. These hypotheses are quite reasonable as there is no reason to have an isotopic fractionation. The problem is then to know the ^{232}Th/^{238}U ratio of the basalts. The weight ratio is given as 2 for mid-oceanic ridge basalts, on average[14], which gives an activity ratio of 0.65. For the only two samples in which radium is present (Table 3) the measured ratios lead to ages of 16 and 12 yr, lower than the ages found with ^{210}Pb.

Recent measurements[15] have shown that tholeitic basalts from 21° N EPR have a higher ^{232}Th content, leading to a mean activity ratio of 1.13, the ages so obtained are respectively 21 and 17 yr. Moreover, in young basaltic rocks, the uranium series may be out of equilibrium, particularily ^{230}Th may be depleted which would imply a higher initial ^{228}Ra/^{226}Ra ratio. Anyway, these ages are too young compared with ^{210}Pb ages. But, due to the uncertainties in the initial ^{228}Ra/^{226}Ra, to the lack of sensitivity of γ rays measurements and to the possible higher mobility of radium isotopes than of lead isotopes, we prefer, until new measurements on well documented samples are obtained, to consider that ^{210}Pb ages are the most probable. It must be pointed out that such low ^{226}Ra activity compared with ^{210}Pb activity have no appreciable influence on ^{210}Pb/Pb ages.

Table 3 Th and Ra isotopic analyses by γ-ray spectrometry

Sample	^{226}Ra (d.p.m. g^{-1})	^{228}Ra (d.p.m. g^{-1})	^{228}Th (d.p.m. g^{-1})	^{228}Th/^{228}Ra	^{228}Ra/^{226}Ra
Alvin 1

923 R7 E	15±1.6	2.3±0.5	3.8±0.7	1.65±0.50	0.15±0.04

Error is 1σ statistical error on counting rate + an error on the efficacy of Ge–Li detector estimated equal to 10%. ^{226}Ra has been measured through ^{214}Bi; ^{228}Ra has been measured through ^{228}Ac; ^{228}Th has been measured through ^{208}Tl.

We conclude that: (1) These dating methods work and their precision may be improved using radiochemical separation followed by α and β countings. (2) There are two well defined systems, one which formed about 4,000 yr ago and another which is active at present. If such systems cannot develop far from the active axis, it shows that during the past 4,000 yr, the spreading rate has been as high as 15 cm yr^{-1}, and not 3 cm yr^{-1}. (3) The active system probably lasts <100 yr, but >20 yr, which is in relatively good accordance with the values calculated in ref. 16 from heat flow theoretical calculations.

We thank Drs J. Labeyrie, J. C. Duplessy and L. Labeyrie Jr for stimulating discussions, and H. Leclaire and J. L. Reyss for collaboration. Also Roger Hekinian for providing the samples, and for cooperation. This study was supported by CNRS and CEA and by ATP Chemical Oceanography grant.

The systematic use of coupled isotopic tracers has improved our understanding of many problems such as the geochemical structure and evolution of the mantle. However, some fundamental questions remain[1–6]; for example, does sediment injection occur in the mantle[4,5,7], modifying composition and combining the internal and external geochemical cycles? Recently ^{3}He data from the South Atlantic have been used to suggest that the sediment injection phenomenon may be important on a local scale[8]. Here, using carbon data only, we show that sediment injection in the mantle must occur. This conclusion was reached after comparison between the integrated flux coming from the mantle and the budget of the exogeneous reservoir of carbon.

The value of the isotopic composition of carbon in the mantle was confusing for a long time. Carbonatites and most diamonds yielded values of δ^{13}C between −9‰ and −2‰ PDB (refs 9–12) whereas basalts yielded values between −25 and −30‰ (refs 12–14) (Fig. 1). Although they exist for a variety of acid residues from continental alkali rocks down to −30‰ (ref. 13), we are not aware of δ^{13}C lower than −26.5‰ for MORB tholeiites[15]. The difference between these values is of the same order of magnitude as that between reduced and oxidized forms of carbon (coal and carbonates) present at the Earth's surface—in low temperature conditions where carbon isotopic fractionation is important[16]. The results for basalts are rather surprising considering that they are formed at high temperature and could imply that the ^{13}C/^{12}C of the mantle is very heterogeneous. This situation has recently been clarified[14,15,17]. The CO_2–liquid melt carbon isotopic fractionation has been measured experimentally[15] and varies from 4.5 to 4‰ between 1,180 and 1,280 °C. Thus, if a basalt of initial δ^{13}C around −7 reaches the surface after losing CO_2, the latter is enriched in the heavy isotope and the basalt contains residual carbon of much lower δ^{13}C.

Both the carbon isotope compositions of several fractions of oceanic tholeiites[15] and of the peculiar types of tholeiites forming the popping rocks dredged on the Atlantic ridge[14] are compatible with this mechanism.

The quantitative model suggested for this outgassing is based on the calculation of the fraction of degassed carbon (relative to the original amount). Using a Rayleigh[14,15] distillation law, a relation between the isotopic compositions of the residual basalt (δ) and of the initial mantle (δ_0) can be written as

$$\delta - \delta_0 = 1{,}000(\alpha - 1)\ln f$$

with α the fractionation factor and f the carbon fraction remaining in the basalt.

Using the experimental values of $\delta_0 = -7$ and $1{,}000(\alpha - 1) = 4.5$ one may calculate a series of values for f corresponding to the different values of δ^{13}C for basalts. The commonly accepted value of $\delta^{13}\text{C} = -26‰$ corresponds to $f = 0.014$. With carbon contents of the rocks between 100 and 150 p.p.m. (ref. 14), this corresponds to an initial content of 6,800–10,200 p.p.m. In fact, δ^{13}C of residual carbon are not necessarily as low as −26‰ and distillation effects do not necessarily follow a Rayleigh model. A greater range of initial contents, of 2,000–10,000 p.p.m., is indicated by recent results[18].

One may now look at the rate of degassing per year. The thickness of the basalt layer in the oceanic crust is 2 km whereas the total thickness of the crust (basalt + gabbro) which was initially liquid, is 5 km. One may consider either that all the liquid has been degassed, directly or through intense hydrothermal circulation at ridges, or only the basaltic layer. This corresponds to two extreme hypotheses.

Considering a constant average spreading rate of 4 cm yr^{-1}, we get:

$$\underset{\substack{\text{(Length}\\ \text{of}\\ \text{ridge)}}}{\begin{matrix}6\times10^{9}\times\\ \text{cm}\end{matrix}} \quad \underset{\text{(Spreading)}}{\begin{matrix}(4\times2)\\ \text{cm yr}^{-1}\end{matrix}} \times \underset{\substack{\text{(Thickness}\\ \text{of}\\ \text{material}\\ \text{involved)}}}{\begin{matrix}2\times10^{5}\\ \text{cm}\\ \text{or}\\ 5\times10^{5}\\ \text{cm}\end{matrix}} \times \underset{\substack{\text{(Density}\\ \text{of}\\ \text{basalt)}}}{\begin{matrix}3\\ \text{g cm}^{-3}\end{matrix}} \times \underset{\substack{\text{(Carbon}\\ \text{concen-}\\ \text{tration}\\ \text{degassed)}}}{\begin{matrix}0.01\\ \text{or}\\ 0.002\end{matrix}} \quad \begin{matrix}7.2\times10^{14}\\ \text{g yr}^{-1}\\ =\\ 0.58\times10^{14}\\ \text{g yr}^{-1}\end{matrix}$$

The total mass of sediments at the Earth's surface is 32×10^{23} g, 15% of which are carbonates. This amount of carbonates corresponds to 5.75×10^{22} g of carbon[16,17].

The mass of the continental crust is 2.4×10^{25} g (ref. 19). Considering a complete granito-gneissic composition and using an average content of 300 p.p.m. carbon for these rocks[20], the granito-gneissic continental crust corresponds to 7.2×10^{21} g which is one hundredth of that present in the sediments and is thus negligible. However, considering the existence of metamorphic carbonated series which are omitted from this calculation, we must add $\sim1\times10^{22}$ g.

The maximum total carbon now present at the Earth's surface is 8×10^{22} g (the amount of carbon in the atmosphere and the oceans is negligible in this context). This gives lifetimes of carbon in the external cycle of $1.1\text{–}14\times10^{8}$ yr. (External is the cycle outside the solid Earth and includes hydrosphere, atmosphere, lithosphere and sediment, but internal includes cycles inside the Earth.) However, the extreme values which cumulate the uncertainties on initial contents and thickness of

0028–0836/82/450171—03$01 00

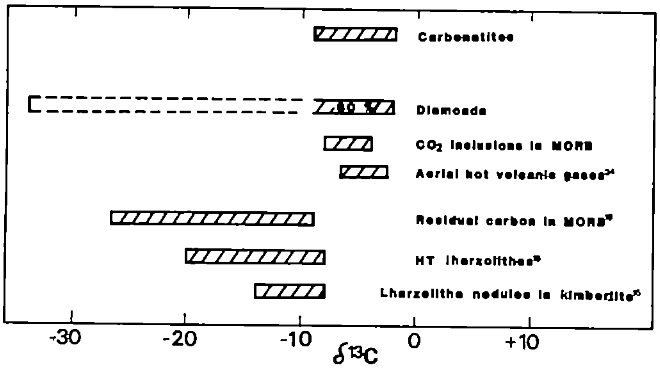

Fig. 1 The different ranges of values of $\delta^{13}C$ for various mantellic materials.

$$\delta^{13}C=\frac{(^{13}C/^{12}C)_{\text{sample}}-(^{13}C/^{12}C)_{\text{standard}}}{(^{13}C/^{12}C)_{\text{standard}}}\times 10^3$$

Standard is the PDB limestone. Results are from refs 12, 15, 18, 34, 35.

material involved are probably over-pessimistic, and the use of the mean rate value (3.9×10^{14} g yr^{-1}) which gives a lifetime of 2×10^8 yr is probably more realistic. Another way of expressing this result is to measure how much carbon has been degassed during 4×10^9 yr thus gaining information on the internal history of the Earth. Using a steady-state hypothesis, we get a mean value of 1.8×10^{24}, which represents 22 times the carbon now contained in the external parts of the planet.

We have considered a steady-state regime for the degassing during geological times but specialists agree that the latter decreased following weakening of the convection throughout this period.

One way of reconciling our observations is to admit that the exogenous cycle does not represent a reservoir of accumulation but of exchange. The carbon would thus be injected in the mantle at subduction zones, within the sediments.

Many objections have been made to the idea. How could light and soft sediments sink into a dense, hard and hot mantle?

The development of deep-sea drilling projects JOIDES and IPOD showed that some subduction zones did not have accretion prisms[21–23] and that generally their tectonic regime was of extension type. Using all types of geophysical and geological information, Uyeda and Kanamori[24] have classified the subduction zones into two types: Chile and Mariana type. For the latter, an extension occurs behind the subduction zone and then sediment injection is a possible mechanism. This process seems the most likely when considering a dynamic process for the subsidence instead of a forced injection of the subducting plate. This injection is not uniform, as shown by the JOIDES drills; some subduction zones, because of their strong distension, allow a fast injection (Central America, Marianas) whereas others with weaker distension produce accretion prisms (Caribbean, Java)[24,25]. The variable intensity of the subduction processes and the distribution of subduction zone may create important geographical heterogeneities in the mantle.

Part of these sediments contaminates the arc volcanism as demonstrated by Kay[26], but an important part sinks into the mantle. When considering a 500–1,000-m-thick layer of pelagic sediments of average density 2.5, the same spreading characteristics used for ridges, a content of 30% carbonates and 1.5% organic carbon, we get $2.8–5.6\times10^{14}$ g of injected carbon. This corresponds to the value already obtained for degassing, by a completely independent calculation.

Therefore, we may conclude that in the present conditions, the exogenous–endogenous cycle in the mantle is a steady state. Using the mean value of 4×10^{14} g for the exchange flux in both directions the lifetime of carbon in the exogenous cycle is $\tau_{ex}=2\times10^8$ yr. Let us now calculate the residence time in the endogenous cycle. Considering that the convection system related to the plate motion only affects the upper mantle, as shown by isotopic and fluid mechanics studies, the mass of mantle material involved is 1×10^{27} g. The carbon content of peridotites, for which $\delta^{13}C$ ranges from −12 to −7 (that is, primitive values), averages 400 p.p.m. (ref. 27). This corresponds to a carbon content of 4×10^{23} g for the upper mantle. The residence time of carbon in the upper mantle is thus $\tau=1\times10^9$ yr, five times longer than in the exogenous cycle.

These very short residence times are useful for explaining the present steady state. When calculating the residence time of the oceanic lithosphere in the mantle, we get $\tau=3.7\times10^9$ yr (ref. 7). Thus, the residence time of carbon in the mantle is shorter and we must admit a much greater mobility for this element. This can be explained either by the fact that carbon is in the form of fluid (CO_2) for which the rate of transfer is large relative to the diffusion coefficient in solids, or in the form of atomic carbon, in defects, which Freund[28] has shown to be very mobile.

The mass injection of carbonates also explains the presence of CO_2 in the mantle, and the evidence[29] for CO_2 has been used elsewhere[30–33] in petrological considerations. If the geodynamical behaviour of water in the mantle is similar to that of CO_2 and particularly its residence time, we may deduce important geochemical consequences: the H_2O/CO_2 ratio in the upper mantle could be equal to the chemical ratio during injection. The carbon and water contents of injected sediments average 4.5 and 3% respectively, so that the contents in water and carbon introduced through hydrothermal circulation in the

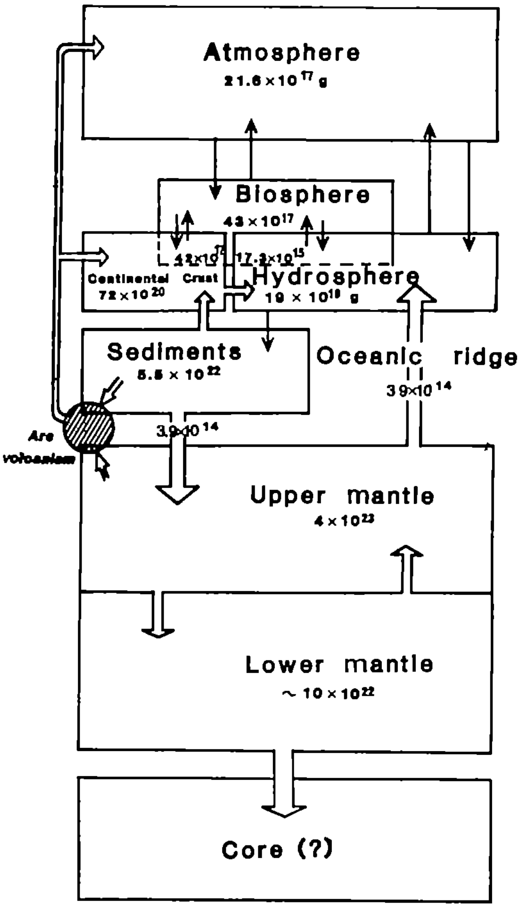

Fig. 2 Box model showing the different reservoirs for carbon and their mutual relationship. As our main interest is the exchange between exogenic and endogenic cycles, we have simplified the exogenic cycle. The masses of carbon in the reservoirs are expressed in grammes, those for the flux of exchange are in grammes per yr.

oceanic crust are 2 and 0.2% respectively. Considering a 2-km thick basaltic layer, we get 8.6×10^{14} g of water and a H_2O/CO_2 ratio in the mantle of 1.8.

We have neglected an important gas loss at volcanic arc areas—an acceptable approximation if considering a steady state. However, in future we will have to take this arc volcanism into consideration. In the steady-state hypothesis, we have the following equation for flux

$$F_{\text{ridge}}+F_{\text{arc}}=F_{\text{sediment}}$$

but the error on F_{sediment} and F_{ridge} is much too large and we cannot directly measure F_{arc}. No account has been taken for the moment of possible but unknown exchange between upper and lower mantle. Figure 2 shows the relationship proposed between these various reservoirs.

We have demonstrated that the mantle is degassing large amounts of CO_2 and H_2O. The study of isotopic composition of rare gases such as xenon and argon showed that the Earth has been suddenly degassed for ~95% in its first 50 Myr (ref. 6). If, as generally assumed, the carbon were present in the form of CO_2 and CH_4 in the atmosphere one may consider that carbon has been expelled from the mantle during this period. Thus, the exogenous reservoir of carbon was five times larger at this time than it is at present, and consequently the CO_2 content of the upper mantle much lower.

The sediment recycling began re-equilibrating both reservoirs as soon as carbonates formed in the primitive ocean and then the content of carbon in the mantle tends to increase when the content of CO_2 in the exogenic cycle decreases. At present, it is difficult to quantify such an evolution.

We point out the different history for the various mantle gases. For some of them, which are not carried heavily by sediments or subducted slabs, like probably Xe or Kr, their origins are residual after mantle outgassed. For some others, like CO_2, they are completely recycled. In this respect it would be interesting to study the behaviour of N_2 or Cl for which recent studies seem to indicate an interesting recycling history. This comparative volatile geochemistry would enable us to reconstruct the history of the atmosphere, and also of sediment recycling and mantle history.

Isernia La Pineta central Italy is an extensive open-air archaeological site of early Lower Palaeolithic aspect. Radiometric and palaeomagnetic dating place it in the Matuyama reversed epoch, hence before 0.73 Myr. Its early date, stratified context, abundant stone tool industry of choppers and flakes and rich faunal remains make it one of the most important localities for the question of the earliest human colonization of Europe. The archaeological horizons (Fig. 1) were discovered during recent road-building operations at 4 m below surface near the city of Isernia (Upper Volturno Basin, Province of Molise; see Fig. 2). Excavations in 1979 and 1980 carried out in two areas (sectors I and II; Fig. 2) revealed dense scatters of limestone choppers, flint flakes and disarticulated bones of large mammals. Similar occurrences have been found elsewhere in the valley. Previous accounts[1,2] are revised herein.

The archaeological levels are contained in fluvial and fluviolacustrine sediments pertaining to the principal fill of the Isernia Basin (Fig. 3)[3]. A lacustrine facies, evident at the base of this unit, ends in the north-east of the basin with banks of travertine often several metres thick. The principal fill covers depressions in a Pliocene erosional surface which retained some gradient as late as the early Pleistocene. Tectonic movements

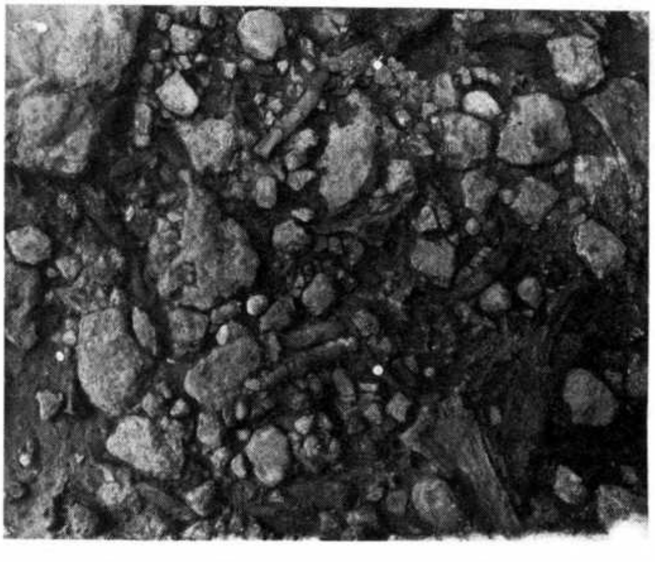

Fig. 1 Isernia La Pineta. Portion of archaeological horizon, sector I.

0028-0836/82/450173—04$01.00

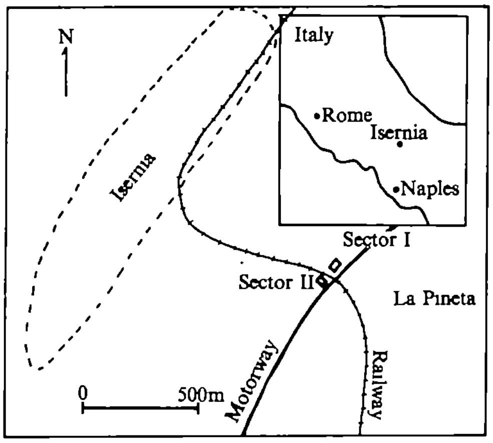

Fig. 2 Study area location map.

connected with vulcanism disrupted this surface in the middle Pleistocene, causing a considerable increase in gradient and the deposition of coarse fluvial sediments.

Numerous beds of tuff are intercalated within fluvial layers of the principal fill[4]. Grey tuffs, poor in pumice and sanidine, are found even in the lowermost lacustrine series. At higher elevations in the series tuffs are mostly brown in colour; they are partly redeposited, but all are rich in sanidine and contain crystals of biotite and pumice fragments up to 1 cm in diameter. It is thought that the volcanic activity responsible for the deposition of these tuffs took place at the same time as that of the nearby Rocca Monfina system.

Important neotectonic movements developed in the Isernia Basin, following Appenninic and anti-Appenninic directrices. Their most obvious effects consist of impressive stream capture and fault movement, involving surface rocks and/or Pleistocene deposits.

The Palaeolithic levels under consideration are sandwiched between the latest episodes of lacustrine sedimentation and the earliest fluvial deposits. The lower of the two archaeological layers encountered in sector I rests directly on a bed of travertine which shows signs of pedogenesis at its upper surface. A mantle of fluviatile muds, on which the upper occupation surface lies, covers the travertine. The upper archaeological surface was buried by sediments directly tied to an emission of tuff. The physical condition of the volcanic minerals, mainly pyroxenes and sanidines, excludes the possibility of significant fluvial transport. Fluvial sands and gravels were subsequently deposited, intercalated with tuffs and palaeosols.

From the geostratigraphical standpoint the archaeological levels seem to represent brief events, whereas the sedimentary facies in which they are included were deposited over a longer time interval.

Recent studies suggest that the Rocca Monfina volcano, whose activity had a strong influence on the Isernia basin, was active from ~1.54 to 0.34 Myr (ref. 5). K–Ar dates obtained by the Amsterdam laboratory[6] indicate that the first major phase of tuff deposition in the Isernia/Upper Volturno basin took place ~0.87–0.84 Myr.

A particularly distinctive feature of the latest depositional phase of the Isernia basin principal fill was a blanket of yellow tuff, found throughout the basin[4]. Two samples of sanidines from the yellow tuff in the Isernia La Pineta series, dated by the University of Rome laboratory, gave ages of 0.55 ± 0.05 and 0.47 ± 0.05 Myr (Fig. 3*B*), not significantly different.

A sample of the sediments immediately overlying the upper archaeological level in sector 1 gave an age of 0.73 ± 0.04 Myr. This date can be regarded as dating the archaeological level itself, as these sediments, directly tied to volcanic activity, buried the archaeological surface in a very short time. In view of the indications that the fluvial material from the top of the archaeological horizon up to tuff II was deposited rapidly, this age is also in stratigraphical agreement with the date of 0.73 ± 0.07 Myr obtained by the Amsterdam laboratory. The sample (biotite) that gave the latter date was collected from a tuff in the Belfiore series (Fig. 3*B*) ~ 1 km north of the Isernia La Pineta section. The tuff is stratigraphically equivalent to tuff II at the latter section[6].

Palaeomagnetic dating was done at the University of Pittsburgh. Oriented samples were measured in a cryogenic magnetometer. Polarities range from 'clearly reversed' to 'possibly reversed' and 'indeterminate' (because of heavy present field overprinting). No sample showed unambiguous normal polarity, so it is probable that deposition of the sediments sampled, and thus the archaeological layers as well, date to the Matuyama reversed epoch. There are no minor reversed episodes or excursions within the earlier half of the Brunhes to which the sample polarities could alternatively be ascribed. An attempt is being made to locate the Matuyama–Brunhes interface in the series.

The age indicated by palaeomagnetism and K–Ar (late early Pleistocene) is older than the age customarily ascribed to the Isernia fauna, and leads to doubts regarding the age of that faunal assemblage.

The archaeological layers have yielded a large sample of faunal remains, still in process of study. The materials from sector I, which are the better preserved, are being restored *in situ* and studied in detail as conservation is completed and they are removed.

The material from sector II consists of skeletal remains of large mammals, principally bison, bear, elephant, rhinoceros and hippopotamus. The parts represented, all fragmentary and mostly incomplete, include vertebrae, ribs, scapulae, pelves, crania, and epiphyses of long bones. The only complete parts are teeth, second and third phalanges, carpals and tarsals—all parts that lack marrow.

The faunal material from sector I, mostly complete bones, is represented predominantly by crania of bison and a significant number of cranial and dental remains of the other large mammals. The long bones are mainly of elephants.

The large number of bones represent a small number of mammalian species. Most frequent is bison (*Bison* cf. *schoetensacki* Freudenberg), followed by rhinoceros (*Dicerorhinus* cf. *hemitoechus* Falconer), elephant (*Elephas antiquus* Falconer), and bear (*Ursus deningeri* von Reichenau); *Hippopotamus* sp. cf. *amphibius* L., *Sus scrofa* and *Hemitragus* sp. are rare. Cervids are represented by possibly a single *Dama* individual.

A few rodent bones were recovered from water-sifted fine sediments in the fauna-bearing layers. Because of scarcity and poor preservation, only a few isolated teeth could be identified (Fig. 4). The species represented are *Clethrionomys* sp., *Microtus arvalinus* Hinton, *Pitymys* cf. *arvaloides* Hinton, *Arvicola* cf. *mosbachensis* Schmindtgen, *Pliomys episcopalis* Meheley, and *Pliomys lenki* Heller.

The megafaunal assemblage has hitherto been ascribed to the middle Pleistocene. The micromammals, however, although scanty, confirm the indications from palaeomagnetic and radiometric dating that human activities at the site took place in the late early Pleistocene.

The low frequency of cervids—ordinarily the commonest large mammals encountered in middle Pleistocene faunas of the Mediterranean basin—calls for an attempt at explanation. The situation might be attributable to selection on the part of the hunters for animals with a greater meat yield, but the picture obtained from study of other Pleistocene sites is one in which hominids hunt all ungulates present in a region, with the result that the fauna reflects, if imperfectly, the real faunal population. Only carnivores are normally under-represented in human cultural deposits. Bears are an exception, but even their proportion is considerably lower than that of ungulates and other animals.

The tentative conclusion is that a specific climatic type with two seasons is represented at Isernia La Pineta: a brief wet

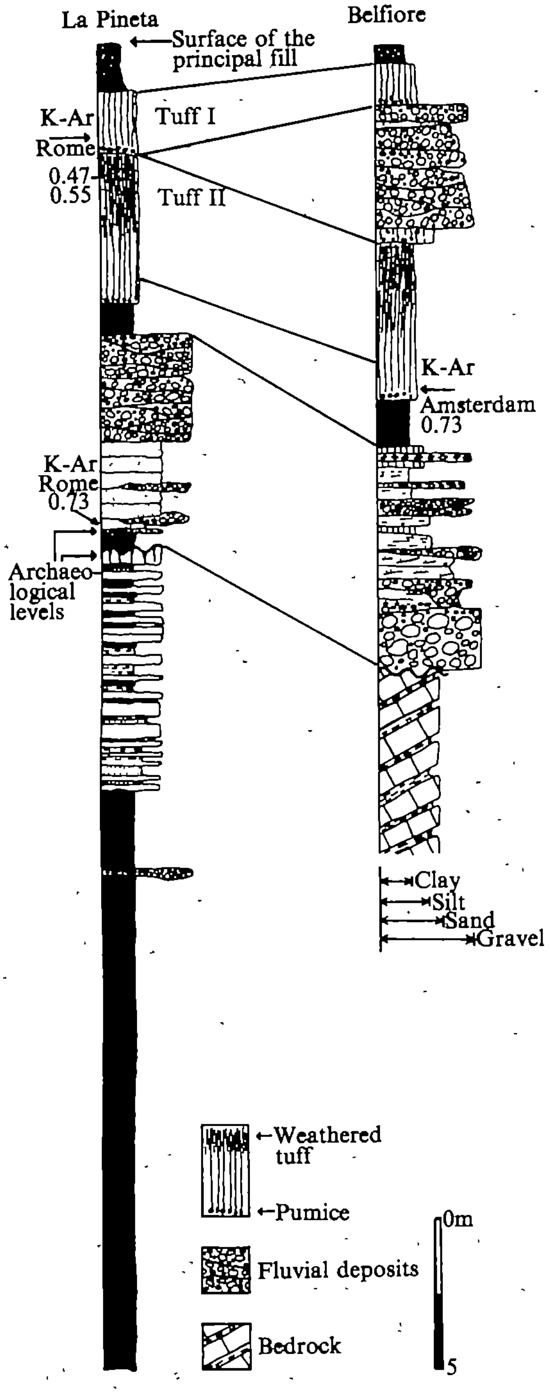
B



season and a much longer arid season, resulting in an open steppe or grassland-steppe environment, well suited to a variety of pachyderm and bison species.

A continental molluscan fauna was studied from a clayey layer $\sim$12 m below the upper archaeological horizon[7]. The species found are *Lymnaea truncatula*, *Vertigo pygmaea*, *Vertigo moulinsiana*, *Pupilla muscorum*, *Vallonia pulchella* and *Succinea oblonga*. Molluscan associations of this kind characterize both middle and late early Pleistocene cold phases of Central Europe.

In sector II, an archaeological horizon of $\sim$70 m^2 was excavated. It had undergone weathering, which advanced the partial decalcification of the bones. Areas were encountered with heavy concentrations of lithic artefacts, most of small size. Tools include denticulates, notches, 'Tayacian'-like points (including some with dihedral ventral surfaces) and rare scrapers. There was a near absence of choppers. The faunal remains associated with the lithic scatters include a few fragments of diaphyses, mostly of small size and poorly preserved, and dental remains of bison, rhinoceros, elephant and bear.

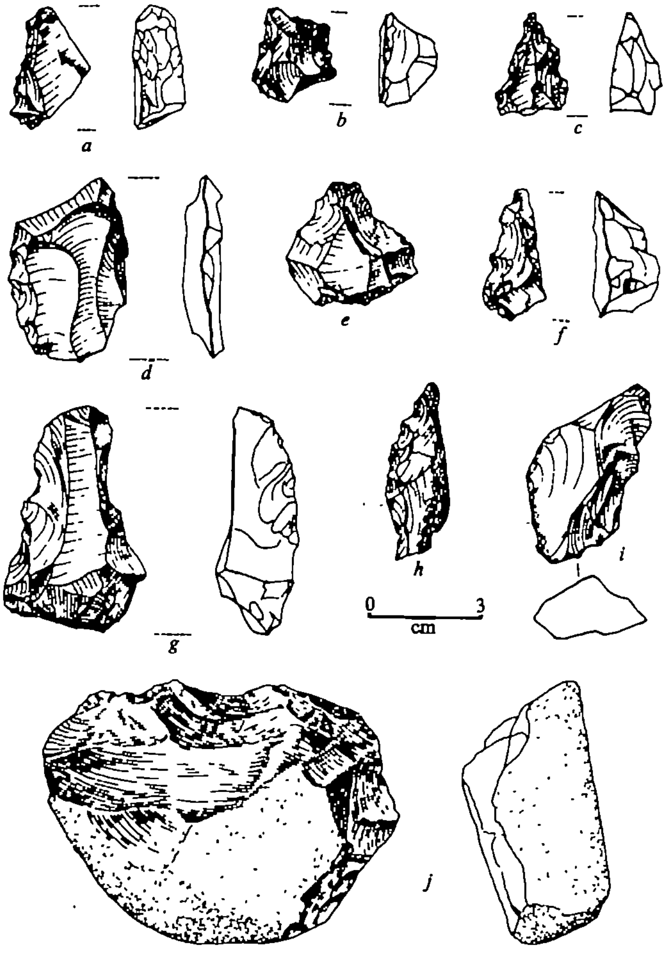

Fig. 5 Isernia La Pineta. Artefacts: *a–i*, denticulate tools on flint flakes; *j*, limestone chopper.

About 53 m^2 have been exposed in sector I. Several large blocks of limestone and travertine lay on the archaeological surface, which was covered with the bones of large mammals, with stone tools scattered among them. The disposition of the stone blocks and faunal remains strongly suggests human intervention. The faunal parts present are highly non-random. There were some 20 crania of bison; crania, mandibles and teeth of rhinoceros, hippopotamus and bear; tusks, molars and long bones of elephants. The stone tools—numbering in the thousands—can be divided into two major categories (Fig. 5). Choppers, nearly all of limestone river pebbles or cobbles, were highest in frequency. The other category comprises flake tools of flint, all much smaller than the choppers. Some can be identified as denticulates; there were only a few scrapers. Many were utilized but unmodified.

In 1980, an earlier cultural horizon was encountered in sector I beneath the one just described, separated from it by ~50 cm of culturally sterile deposits. This earlier layer, considerably lower in density of cultural materials than the one overlying it, rested on a bank of travertine. The lithic industry and faunal remains were in all respects similar to those from the upper layer.

It is not easy to find comparable sites for discussion. The few that have been ascribed to a similar age either yielded poor or ambiguous artefact inventories or do not clearly indicate a human presence. Others are surface scatters or lack secure provenience in some other way. Some of them are discussed elsewhere[8,9]. The more secure of them at least support the existence of a non-Acheulian industry in the late early Pleistocene.

We thank A. Gubellini, G. Lombardini and P. Russo of the Institute of Topography of the University of Bologna for planimetry and stereophoto coverage of the archaeological surface. Palaeomagnetic dating was aided by financial assistance from the National Geographic Society. Authors' specialities: M.Co., geomorphology; M.Cr., pedology and stratigraphy; M.C.D. A ziphodont mesosuchian crocodile from the Eocene of Algeria and its implications for vertebrate dispersal

E. Buffetaut

ERA 963 du CNRS, Laboratoire de Paléontologie des Vertébrés, Université Paris VI, 4 place Jussieu, 75230 Paris Cedex 05, France

Fossils from a newly discovered, probably middle Eocene locality in southern Algeria provide the first evidence of an African terrestrial mesosuchian crocodilian with a ziphodont dentition (that is, with compressed, serrated teeth). Ziphodont mesosuchians were previously known mainly from South America and Europe, but have not been reported from North America. Several other groups of land vertebrates show a disjunct distribution in the Palaeogene, with representatives in Europe and South America, but no certain record in North America, where they should occur if, as has been suggested, dispersal had taken place from South America to Europe across North America. The discovery of a ziphodont mesosuchian in Algeria is the first tangible evidence that may support the alternative hypothesis of faunal connections between South America and Europe via Africa.

The crocodilian material described here was collected from the newly discovered El Kohol locality, near Brezina in southwestern Algeria, which is being excavated by a team from the universities of Paris and Oran under the direction of J. J. Jaeger. The continental vertebrate fauna, which is still being studied, includes a lungfish, a crocodilian, and various mammals (hyracoids and a form related to *Barytherium*). It seems to indicate an age older than the lower levels of the Fayum, possibly middle Eocene.

The crocodilians are represented at El Kohol by lower jaw fragments, isolated teeth, vertebrae and a fibula. The vertebrae are amphicoelous, which is indicative of the archaic suborder Mesosuchia. The fibula is elongated and slender, which may be related to a mainly terrestrial way of life. The teeth are especially interesting. They are definitely compressed laterally (although not as much as in some other ziphodont crocodilians) and bear two sharp, finely serrated carinae; the more posterior ones are rather blunt, with a finely wrinkled enamel, while the anterior ones are more pointed, with less distinct wrinkles. Two lower jaw fragments are available: one is an almost complete

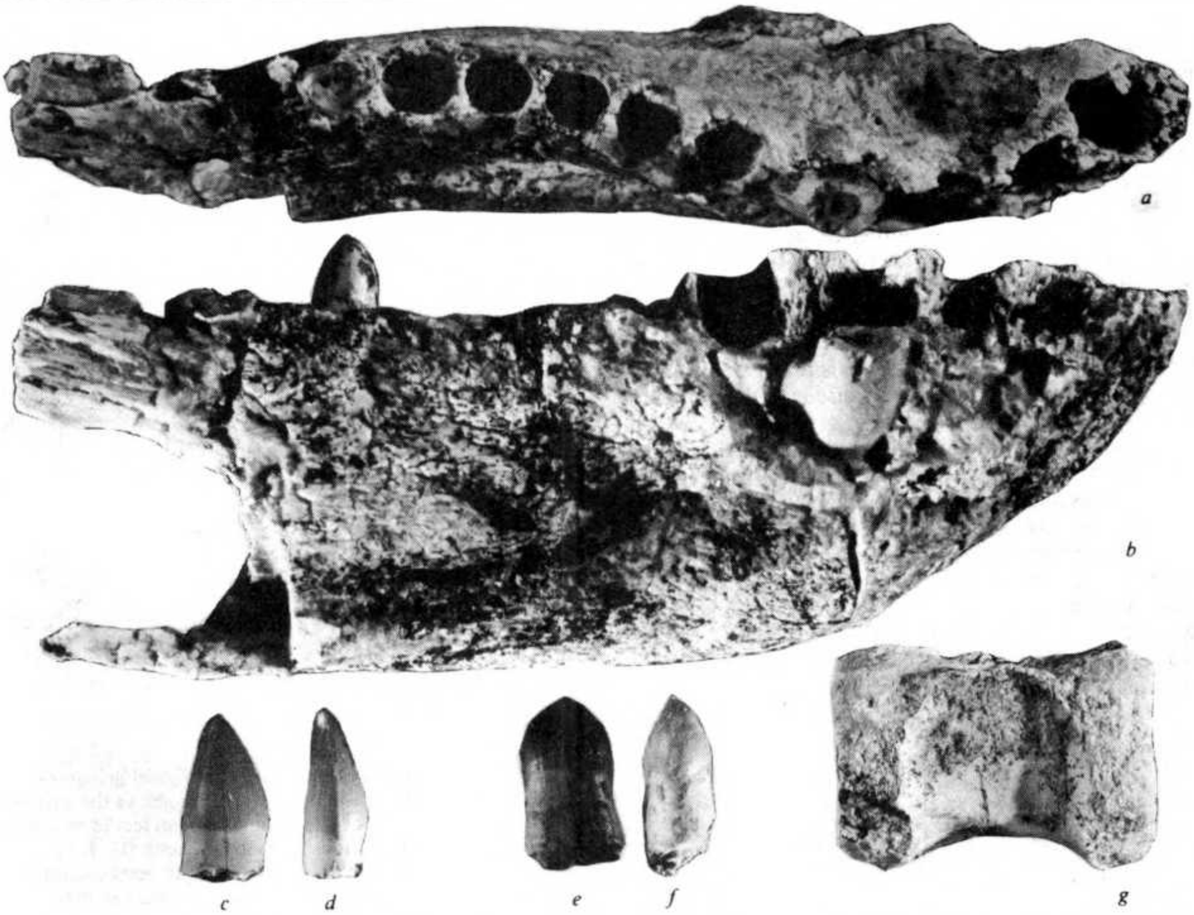

Fig. 1 Remains of a ziphodont mesosuchian crocodile from the Eocene of El Kohol, Algeria. *a*, *b*, Right dentary in dorsal (*a*) and lateral (*b*) views; *c*, *d*, two views of an isolated anterior tooth, showing lateral compression; *e*, *f*, two views of a posterior tooth, showing a blunt apex; g, lateral view of an amphicoelous caudal vertebra. ×1. (Photographs by C. Abrial.)

right dentary, still bearing one complete tooth similar to the isolated ones described above, the other is the back part of a left mandibular ramus with the articular region. The dentary is remarkably deep and laterally compressed; its lateral surface shows a marked concavity. It bears 12 alveoli arranged in a sinuous row; the fourth alveolus is the largest. The dentary symphysis reached the level of the fifth alveolus, and the splenials too apparently took part in the symphysis. The articular region of the other jaw fragment is remarkable mainly because the surangular takes part in the jaw articulation.

The affinities of this ziphodont mesosuchian, which undoubtedly represents a new taxon, are still difficult to determine with complete accuracy. The depth of the dentary is reminiscent of the sebecosuchian *Baurusuchus*, a ziphodont mesosuchian from the Upper Cretaceous of Brazil[1]. The articular region of the mandible is similar to that of *Sebecus*, a Tertiary sebecosuchian from South America[2], but it also closely resembles that of *Trematochampsa*, a non-ziphodont mesosuchian from the Upper Cretaceous of Niger and Madagascar[3,4]. Although they are compressed and more distinctly serrated, the teeth too are somewhat reminiscent of the Trematochampsidae. Comparison with the few known ziphodont mesosuchians from Europe is difficult. The lower jaw of the Algerian form is quite unlike that of *Bergisuchus dietrichbergi* from the middle Eocene of Germany[5]. In *Iberosuchus macrodon*[6], from the Eocene of Portugal and Spain, only the upper jaw is known. It should also be mentioned that the vertebrae from El Kohol are similar to those of a still undescribed ziphodont mesosuchian from the late Eocene of La Livinière (Hérault, southern France).

The biogeographical interpretation of the crocodilian from El Kohol depends on the phylogenetic relationships between the ziphodont mesosuchians of South America, Africa and Europe. Independent evolution of the European forms is rather unlikely, for lack of suitable local ancestors. On the basis of the available material, however, the hypothesis that ziphodont mesosuchians appeared independently in South America and in Africa cannot be completely dismissed. The alternative hypothesis is that all three geographical groups are closely related, or, in other words, share a common ziphodont ancestry. Although the details of the phylogenetic history of these crocodilians and their systematic expression have still to be worked out, this more parsimonious interpretation of the record does not seem to be definitely contradicted by anatomical or chronological data. Pending future discoveries, it can be accepted as a working hypothesis that the South American Sebecosuchia, the El Kohol crocodilian, and the ziphodont mesosuchians from the European Eocene are closely related forms and not the products of convergent evolution. If this were the case the origin of the European forms would be of great interest.

In recent years, an increasing number of land vertebrates with South American affinities (that is, belonging to groups otherwise known mainly from South America) have been found in the European Eocene, some of which are unknown in the Cretaceous and early Tertiary of North America. Besides the ziphodont mesosuchians, such groups with a 'South American-European' distribution include amphibians (Ceratophryinae)[7], land birds (Phorusracidae)[8], and anteaters (Myrmecophagidae)[9]. A possible explanation for this peculiar distribution is that these groups originated in South America, and then spread to North America by way of a Central American land connection in the late Cretaceous, finally to reach Europe via the North Atlantic lands[6,7,10,11]. Other land vertebrates, such as several groups of snakes[12] and the didelphine marsupials[13], are recorded from the Palaeogene of North America and probably went through such a biogeographical history. However, the main problem about accepting a similar situation for the ziphodont mesosuchians, the Ceratophryinae, the Phorusracidae and the Myrmecophagidae is that those groups have not been reported from the rich and fairly well-known late Cretaceous and Palaeogene fossil localities of North America. It has recently been suggested by C. Mourer-Chauviré[14] that these land vertebrates may have reached Europe from Africa, after differentiating in Gondwana, either before or after South America became separated from Africa (in the latter case, dispersal across the Atlantic may have taken place along the Walvis-Rio Grande rises, which seem to have been subaerial in the late Cretaceous[7]). Evidence for faunal exchanges between Africa and Laurasia in the late Cretaceous and Palaeogene is still scanty, but does exist[14]; the recently discovered continental vertebrate fauna from the Palaeocene of Morocco (which, incidentally, does not indicate affinities with South America) is one of the most important elements in this connection[15]. However, there was hitherto no fossil evidence for the presence of the 'South American' groups of the European Eocene on the African continent. The discovery of a ziphodont mesosuchian in the Eocene of Algeria now seems to provide the first evidence that some of these land vertebrates may indeed have reached Europe from Africa.

I thank J. J. Jaeger for the crocodilian material from El Kohol and for information about that locality.

Competition between female relatives in a matrilocal mammal

T. H. Clutton-Brock, S. D. Albon & F. E. Guinness

Large Animal Research Group, Department of Zoology,
Cambridge CB3 0DT, UK

Evolutionary theory predicts that in sexual organisms the average parents should invest equally in their male and female progeny[1] except where related males compete with each other to mate, when selection may favour parents that produce a female-biased sex ratio[2–4]. It has recently been suggested that in species where daughters adopt home ranges overlapping those of their mothers while sons disperse, competition for resources between female siblings may select for mothers who produce male-biased sex ratios[5]. We show here that in a mammal living in matrilocal, non-territorial groups—the red deer (*Cervus elaphus*)—the presence of resident female relatives depresses the reproductive success of adult females, providing a possible explanation of the apparent bias in parental investment towards male offspring in this species[6].

Red deer hinds on the Isle of Rhum (Scotland) occupy home ranges of around 2 km^2 but spend most of their time within core areas of less than half this size (Fig. 1). Sons disperse from their mother's core area between the ages of 2 and 4 yr while daughters typically adopt core areas that overlap those of their mothers and older sisters. As a consequence of variation in mortality, reproductive success and the proportion of male calves produced, the size of these matrilocal groups ranges over 2–12 breeding hinds. Related females associate with each other throughout their lives, though the core areas of different matrilocal groups overlap extensively and hinds commonly form parties consisting both of relatives and of members of other matrilocal groups.

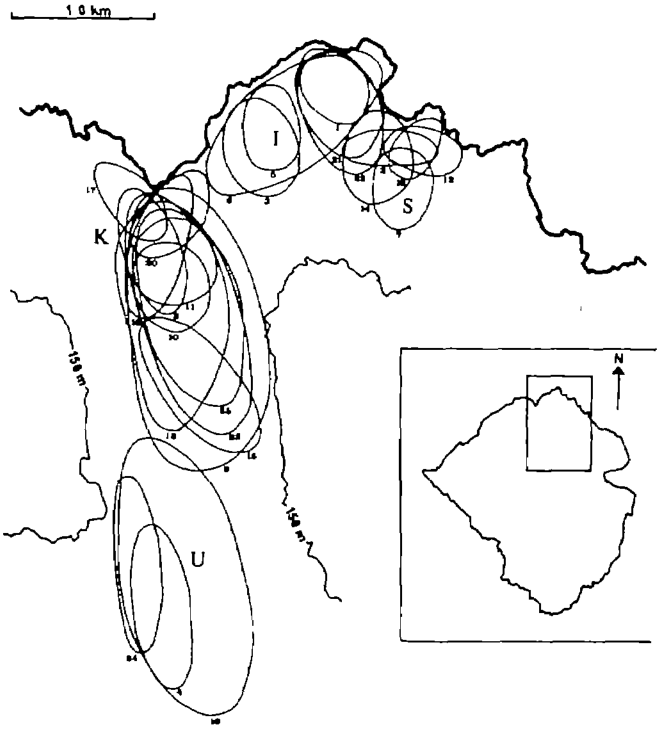

Fig. 1 Core areas of 25 different matrilocal groups of red deer hinds on the Isle of Rhum. Each ellipse shows the smallest area accounting for 65% of all sightings of members of that matrilocal group. The four divisions of the study area (U, K, I and S) are also shown. Numbers on ellipses identify individual groups and do not reflect the number of animals in them.

Records of the reproduction of 43 individually recognizable hinds obtained between 1971 and 1979 showed that hinds belonging to matrilocal groups of above average size were less successful breeders than members of groups below average size (see Table 1*a*), an effect which recurred within all four divisions of our study area (Fig. 2). To check that the negative relationship between group size and reproductive success was not a consequence of any association between the size of matrilocal groups and the number of other deer using their range, we regressed our measures of the mean number of calves reared per year by individual hinds on the number of related hinds seen feeding in their core areas (*a*) and the number of unrelated hinds seen feeding in their core areas (*b*) over a 4-yr period. Reproductive success was only related to the first of these two values (*a*: $r = -0.343$, $t_{38} = 2.249$, $P < 0.05$; *b*: $r = 0.091$, $t_{38} = 0.503$, not significant (NS)). Moreover, the extent to which a group's size increased between the first and second halves of the study period was correlated with the extent to which the reproductive success of its members fell ($r_s = 0.360$, $t_{23} = 1.853$, $P < 0.05$, one-tailed).

The reduction in reproductive success among members of large groups was partly a result of an increase in the age at first breeding (only 47% of their members conceived for the first time as 2-yr-olds compared with 79% of members of small groups), partly of lower fecundity rates over the remainder of their lifespan and partly of increased calf mortality (see Table 1). The most likely cause of the reduction in the reproductive performance of females was increased competition for food between group members: the effects of population density on reproductive performance and survival are pronounced in this

Table 1 Results of studies showing competition between female relatives in red deer

a, Reproductive performance	Large groups	Small groups	
Median no. of calves surviving to 1 yr old reared per yr	0.500 (22)	0.675 (20)	$z = 2.594, P < 0.01$
Median no. of calves born per yr	0.695 (16)	0.847 (16)	$U = 71.5, P < 0.05$
% Male calves dying in first yr of life	36.4 (118)	16.2 (117)	$G = 12.60$, d.f. = 1, $P < 0.001$
% Female calves dying in first yr of life	22.1 (95)	24.1 (87)	NS
% Males dying as yearlings	22.7 (75)	6.5 (98)	$G = 10.19$, d.f. = 1, $P < 0.01$
% Females dying as yearlings	9.1 (75)	9.3 (66)	NS
Birth sex ratio	127:100 $n = 123$	140:100 $n = 142$	NS
b, Kidney fat index	Males	Females	
Calves	1.5	1.6	$n = 26, 24$
Yearlings	1.6	2.0	$n = 38, 36$
2 Yr olds	1.9	3.5	$n = 67, 51$

a, Reproductive performance of hinds belonging to large versus small matrilocal groups (all *P* values two-tailed). A large group was one above the median size for the relevant division of the study area (see Fig. 1), a small group one that was below this size (sample sizes are given in parentheses). *b*, Kidney fat indices (weight of kidneys and perinephric fat divided by weight of kidneys) for calves and yearlings shot in winter in central Scotland (from ref. 9).

population and the frequency of aggressive interactions between hinds was greatest in those parts of the study area where population density was highest[7].

The size of a mother's group influenced the survival of her sons but had little or no effect on the survival of her daughters (Table 1*a*)—although both sons and daughters up to 1 yr old used the same food sources as their adult female relatives[7]. Feeding competition between male offspring and their female relatives was probably the principal cause of the increased mortality of young males in large groups as individuals that died had no more resident male relatives than those that survived (median test $G = 1.495$, d.f. = 1, NS). Reduced survival in conditions of food shortage in adolescent males compared with females of the same age is common among dimorphic mammals[7–13]. One contributory factor is probably the associated tendency for young males to lay down less body fat than females (see Table 1*b*). This sex difference may have evolved because the lifetime reproductive success of males is more strongly influenced by their adult body size than that of females[7], adult size is closely related to early growth and selection may consequently favour the increased allocation of nutritional resources by young males to muscular and skeletal growth instead of to the insurance policy provided by fat reserves[7,17].

We previously[6] demonstrated that in the same population hinds invested more heavily in their sons than their daughters before weaning: male calves sucked more frequently and mothers that had reared sons were less likely to calve the following year and, if they did so, calved later than mothers who had reared daughters. Despite the increased costs of producing male offspring and their higher mortality, the sex ratio of calves at weaning showed a consistent though non-significant bias towards males (118 male:100 female, $n = 347$) and we argued that our results were difficult to reconcile with Fisher's theory that parents should divide their total investment equally between their male and female progeny[1].

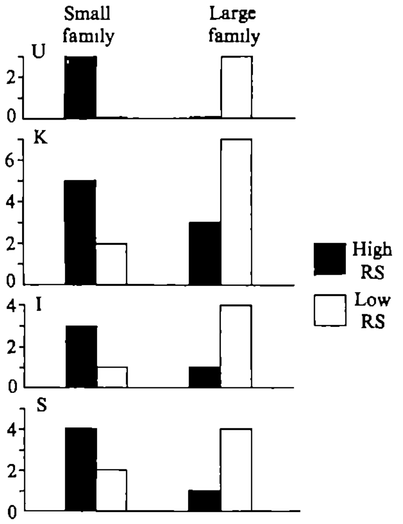

Fig. 2 Number of hinds belonging to large versus small matrilocal groups whose reproductive success (mean number of calves reared per year) are above versus below the average for the division of the study area where their home range was located (see Fig. 1). A large group was one above the median size for the relevant division of the study area, a small group one below this size.

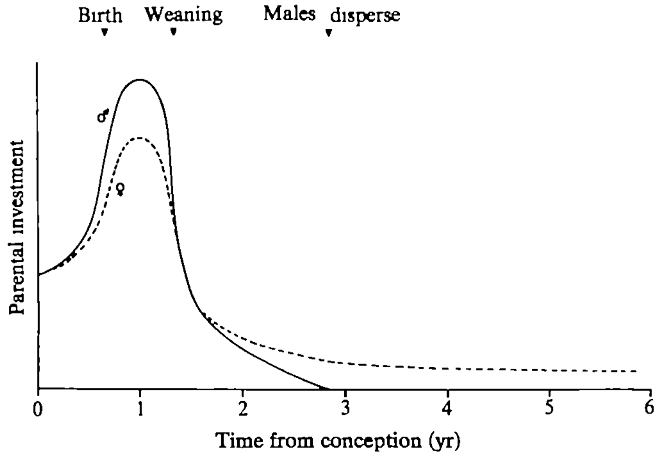

Fig. 3 Hypothetical plot of the changes in the distribution of parental investment[14] by red deer hinds to their male and female calves.

The results described here provide a possible resolution to this problem. Although sons may be more costly to rear than daughters, they disperse widely through the population and competition between adult male siblings either for food or for mates is uncommon. In contrast, daughters adopt home ranges overlapping those of their mothers and compete with each other as the size of the matrilocal unit grows.

The situation can, perhaps, be most easily viewed from the standpoint of the mother, who invests[14] more heavily in her sons than her daughters before weaning but more heavily in her daughters than her sons afterwards (see Fig. 3). This need not imply that mothers treat their daughters differently from other conspecifics (although related hinds do, in fact, tolerate each other in close proximity while feeding[7,15]) because in this context all costs of producing daughters should be considered as forms of investment. The temporal change in the bias of investment is likely to increase the mother's fitness, for our research indicates that the lifetime reproductive success of males is more strongly influenced by their body size and their early growth rates (see above) than by differences in the quality of the home range they occupy as adults, while the reverse is true of females[6,7].

Competition among female relatives for access to local resources[5] is likely to be widespread among mammals because males commonly disperse from their natal area while females remain in the locality where they are born[16]. A recent survey of the available literature shows that significantly male-biased fetal and birth sex ratios are substantially more common than female-biased ones in mammals[17]. However, a possible alternative explanation is that male-biased birth sex ratios have been favoured because they compensate for increased pre-weaning mortality among males[1] which may only occur in populations close to carrying capacity. Unfortunately, insufficient data are available to determine whether male-biased sex ratios are confined to species where daughters seldom disperse from their natal area, as the theory of local resource competition would predict.

We thank the director of the Nature Conservancy (Scotland) for permission to work on Rhum, Mr G. Iason and Mr C. Duck for assistance with field work, and Professor H. Horn, Dr J. Hoogland and Mr S. Dobson for their comments. The Rhum deer project is funded by grants from the NERC, SERC, Leverhulme Trustees and the Royal Society.

Structure of physiologically classified neurones in the kitten dorsal lateral geniculate nucleus

Michael J. Friedlander

Department of Physiology and Biophysics,
University of Alabama in Birmingham, Volker Hall, Room 82K,
Birmingham, Alabama 35294, USA

The mammalian forebrain, including the dorsal lateral geniculate nucleus (LGN$_d$) and the visual cortex, continues both structural and functional development postnatally and is therefore a useful model for the study of developmental processes in the central nervous system (CNS). We report here the first description and comparison of the structural development of individual, functionally identified neurones in the mammalian forebrain. This comparison is made for the three main cell groups of the central visual pathways (W-, X- and Y-cells), in the neonate and the adult. In the adult, these three classes of neurones have different characteristic electrophysiological properties[1-9] and relay information in parallel about different features of a visual scene[8,9] from the retina through the LGN$_d$ to the visual cortex. In addition, each of the three functional cell types has a characteristic structure in the adult[10,11]. By injection of the enzyme marker substance, horseradish peroxidase, into electrophysiologically identified neurones, the present study demonstrates that each of these functional classes of neurones also has a characteristic morphology in the neonate (in the LGN$_d$ of kitten 3–4 postnatal weeks of age). However, striking differences in the rates of maturation are seen. The W-cells are already mature at this age. The X-cells are the least developed. Surprisingly, some Y-cells are mature. Due to the susceptibility of Y-cells to an abnormal visual environment during development[12-18], they had previously been thought to be slower to mature.

Kittens were anaesthetized with 1.5% halothane in a 1:1 mixture of $N_2O:O_2$ for all surgical procedures. All wound margins were infiltrated with 1.0% lidocaine. The kittens were maintained on a 70:30 mixture of $N_2O:O_2$ during the experiment. When an increase in heart rate occurred (above 175 beats per min) 1% halothane was administered for 5–10 min until heart rate returned to normal. Electrophysiological data were not taken during halothane administration. Respiratory control, P_{CO_2} regulation, temperature control, intravenous administration of paralytic solutions, refractions, placement of stimulating electrodes and preparation of recording micropipettes filled with horseradish peroxidase (HRP) have all been described previously[10] for adult cats. The only difference for the kitten experiments was a reduced rate of administration and concentration of paralytic (12.0 mg per kg per h gallamine triethiodide and 0.5 mg per kg per h (+)tubocurarine at 2 ml per h).

Neurones in the LGN$_d$ were initially characterized by extracellular recording. The following physiological parameters were determined for each cell: (1) the position and size of the receptive field, (2) the response type to a stationary stimulus (excitatory response to light onset or offset), (3) the regularity of the response to moving targets, (4) the strength of the receptive field surround, (5) the regularity of the response to repeated presentation of a stationary stimulus to the receptive field centre, (6) the linearity of spatial summation within the receptive field (using a sinusoidally modulated grating pattern on a cathode ray tube at an appropriately high spatial frequency[4,5,8,10]), (7) ocular dominance, and (8) the latency of response to electrical stimulation of the optic chiasm. The cell was then penetrated with the micropipette, and the receptive field properties were rechecked while recording intracellulary[10]. HRP was then injected into the cell iontophoretically. Only one cell was injected in a single electrode penetration and no more than three cells were injected in an LGN$_d$. The kittens were then deeply anaesthetized with pentobarbital and perfused transcardially with a phosphate-buffered 2.5% gluteraldehyde: 1.0% paraformaldehyde fixative 2–10 h after the injections. Tissue preparation and reaction with 3-3′-diaminobenzidine (DAB) were as previously described[10]. In some cases, the Cobolt intensified DAB reaction[19] was used.

Eighteen neurones in the 3–4-week-old kittens were characterized both physiologically and structurally (seven W-cells, seven X-like cells and four Y-cells). Of the seven W-cells (all located in the C-laminae of the LGN$_d$), all had morphological features similar to those of the adult. Five of these seven kitten W-cells were highly responsive to moving targets. They responded in a regular fashion to repeated visual stimuli, with little decline in the vigour of the response from trial to trial. (This early physiological maturation of movement sensitive neurones in kitten C-laminae was also observed by Daniels *et al.*[20].) This was in contrast to many X-like cells in the A-laminae of the kitten LGN$_d$. These X-like cells would cease responding vigorously to visual targets after one to five trials. Five of the seven W-cells responded to a sinusoidally counterphased grating of low spatial frequency (0.2–0.5 cycles per degree at a contrast of 0.6 and a modulation rate of 0.3 Hz). These were the highest spatial frequencies they would respond to. All five

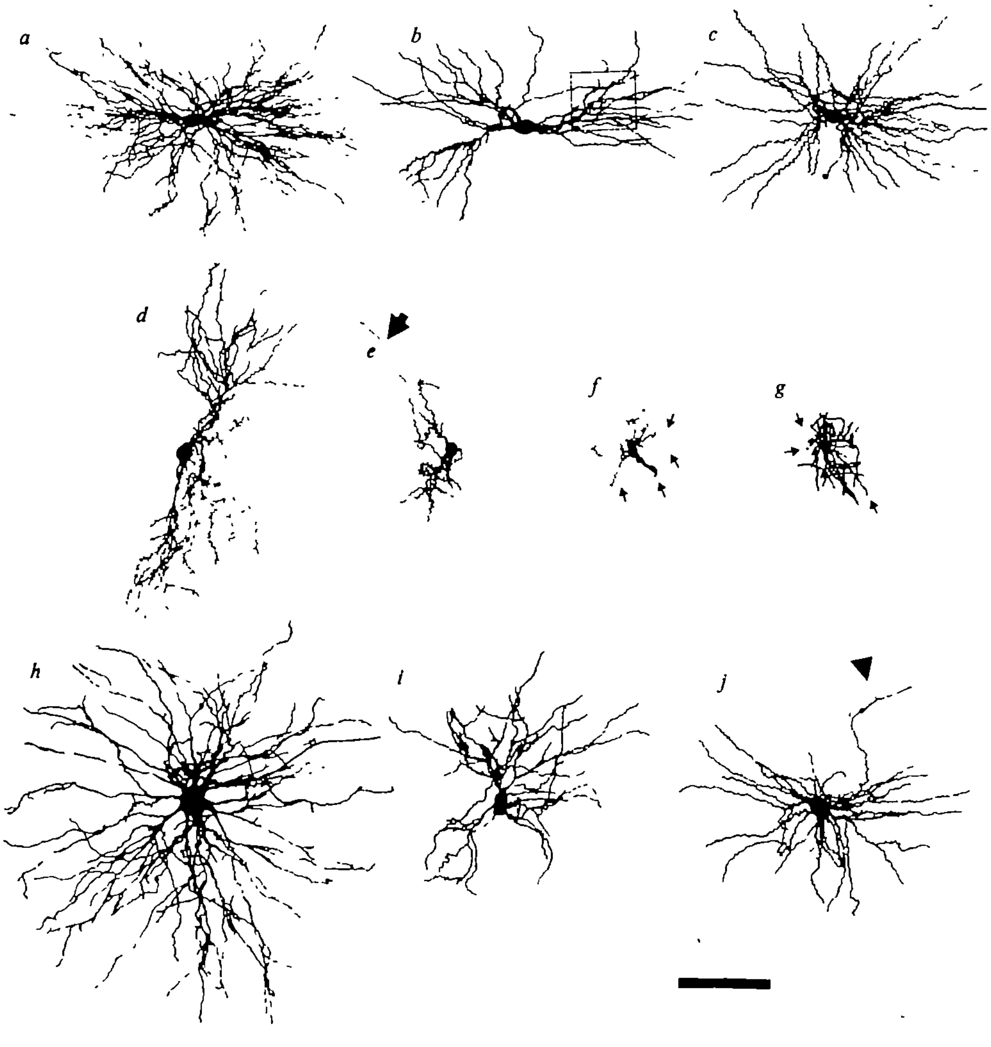

Fig. 1 Drawings of W- (*a–c*), X- (*d–g*), and Y- (*h–j*) cells from the cat dorsal lateral geniculate nucleus (LGN$_d$). *a, d* And *h* are from adult cats. *b, c, e–g*, And *i, j* are from 3–4-week-old kittens. All of the above cells were physiologically classified and then injected intracellularly with horseradish peroxidase. Drawings were made with a × 100 oil objective (numerical aperture = 1.32) and × 10 eyepieces with a drawing tube attachment. A Kodak Wratten 48A deep blue filter was used to enhance contrast when the 3–3′ diaminobenzidine reaction was used to locate the HRP filled cells. *a–c*, W-cells: note the horizontal orientation of the dendritic trees of the typical adult (*a*) and the 3–4-week old kitten (*b* and *c*) W-cells. Note the very similar appearance of the adult and kitten W-cells. *d–g*, X-cells: note the vertical orientation of the dendritic tree of the typical adult (*d*) X-cell. These X-cells in the adult also confined their dendrites to the laminae of origin. The 3–4-week old kitten X-cells (*e–g*) were morphologically immature. The arrow in *e* indicates this cell's axon. This axon had collaterals both within the laminae of origin and above the laminae in the perigeniculate nucleus (PGN). The arrows in *f* and *g* indicate terminal swellings on the ends of the dendrites of two of the very immature looking X-like cells in the kitten. *h–j*, Y-cells: the adult Y-cells (*h*) had large somata, and thick radially oriented dendrites that crossed laminar boundaries. Their axons had collaterals that innervate the PGN. The 3–4-week old kitten (*i–j*) Y-cells had a similar appearance (only smaller). They too had radially oriented dendrites that cross laminar borders and innervate the PGN (arrow in *j*). Scale bar = 100 μm for all drawings and is drawn parallel to the laminar borders of the LGN$_d$.

of these kitten W-cells showed linear summation within their receptive fields. Two of these kitten W-cells are illustrated in Fig. 1*b, c*. Note the W-cell from an adult cat's LGN$_d$ illustrated in Fig. 1*a* for comparison. The dendritic structure of the kitten W-cells is quite similar in orientation and detail to that of the adult. The dendrites are oriented parallel to the LGN$_d$ lamination. In addition to having an adult-like dendritic structure, the somata of the kitten W-cells are large (Fig. 2). The sizes of the kitten W-cells' somata overlap only with the large adult W-cells (range = 210–360 μm^2 in kitten and 80–330 μm^2 in adult). In summary, 3–4 weeks after birth, physiologically identified W-cells are structurally mature, particularly those that are sensitive to moving visual stimuli.

On the other hand, the kitten X-like cells are immature at this age. The seven X-like cells all responded to the sinusoidally modulated grating pattern in a linear fashion[4,5]. All were located in the A laminae of the LGN$_d$. In addition, they all were poorly responsive or not responsive at all to a large target of contrast opposite to their receptive field centre sign moved at moderate speeds (60–100 deg s^{-1}) through their receptive fields. Receptive field surround responses were very weak. No X-like cell responded in an excitatory fashion when the receptive field surround was presented with an annular stimulus of appropriate contrast. However, large stimuli activating both centres and surrounds simultaneously caused a reduced response in all seven X-like cells, indicating an active antagonistic surround mechanism. Latency of response to optic chiasm stimulation overlapped too much between X- and Y-cells in the 3–4-week old kittens to be a reliable correlator with other X- and Y-cell physiological properties. The structure of three of the most physiologically mature X-like cells was like that illustrated in Fig. 1*e*. These X-like cells had receptive field centre sizes ranging over 0.8–1.6°. The cell illustrated in Fig. 1*e* had many complex appendages along its dendrites which were oriented orthogonal to the lamination of the LGN$_d$ (Fig. 1*d* is an example of an adult X-cell for comparison). The other four X-like cells had morphological features that were quite different from any adult LGN$_d$ cells. Two examples of these are illustrated in Fig. 1*f, g*. Note the small dendritic arborizations and lack of obvious vertical orientation. These cells have few appendages along their dendrites. However, the dendrites terminate in swellings (arrows) which may be growth appendages. The four X-like cells with this immature structure were also the most physiologically immature (rapid decrement of a vigorous response to a visual stimulation after only one or two trials with receptive field centre sizes of 2.1–3.5°). The distribution of soma sizes for the kitten X-like cells overlaps only with the lower end of the adult X-cell size range (Fig. 2, range = 80–182 μm^2 in kitten and 80–430 μm^2 in adult). In summary, the X-like cells in the 3–4-week old kitten LGN$_d$ have some mature physiological properties (linear spatial summation and poor responsiveness to fast moving targets) and some immature physiological properties (large receptive field centres, very weak receptive field surrounds and rapid fatiguing of the cells' responses to repetitive stimulation). As a group, the X-like cells are the most anatomically immature cells in the LGN$_d$. Three of seven of these X-like cells had morphological features similar to adult X-cells except for smaller somata and dendritic spread (Fig. 1*e*), while the other four X-like cells had very short dendrites with few typical X-cell dendritic appendages. No X-cells in the

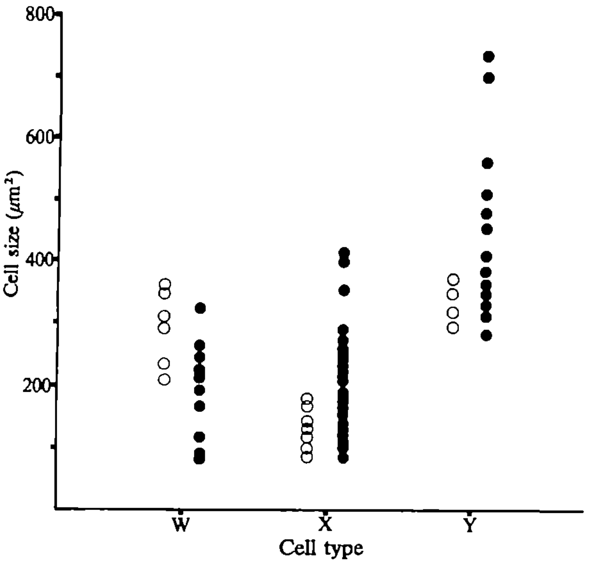

Fig. 2 Distribution of soma sizes for W-, X- and Y-cells in the 3–4-week old kitten LGN$_d$ and the adult cat LGN$_d$. Open circles, kitten cell sizes; filled circles, adult cell sizes. Adult cell sizes are taken from study of Friedlander *et al.*[10]. All cells were physiologically classified and injected intracellularly with HRP. Tissue was vibratomed, reacted with DAB, dehydrated in alcohols and cleared in xylenes in an identical fashion in the kittens and adults. Soma sizes were measured with an electronic planimeter (10 measurements averaged for each cell). Note that the kitten W-cells are as large as the largest adult W-cells, while the kitten X- and Y-cell sizes only overlap with the lower end of the adult range.

kitten or the adult had dendrites which crossed laminar boundaries in the LGN$_d$.

The four kitten Y-cells all responded in a nonlinear fashion to the sinusoidal grating modulation. They all responded regularly to a large visual target moved rapidly through the receptive fields (both of these are features of adult Y-cells[10]). Repeated presentation of stationary visual stimuli elicited consistent responses from the Y-cells. This is in contrast to the X-like cells, which fatigued readily. The Y-cells responded to appropriate stimulation of the receptive field surround in an excitatory fashion. In addition, simultaneous activation of receptive field centres and surrounds antagonized the response. These properties are similar to adult Y-cells. All of the Y-cells were located in the A-laminae as were the X-like cells. Two of these kitten Y-cells are illustrated in Fig. 1*i*, *j*. Note the adult Y-cell in Fig. 1*h* for comparison. These physiologically mature Y-cells of the kitten are similar in morphology to their counterparts in the adult. However, note that the size of the somata and area covered by the dendrites is somewhat smaller than in the typical adult Y-cell. The dendrites of all four kitten Y-cells crossed laminar borders in the LGN$_d$ as did the dendrites of 18 of 19 of the adult Y-cells. In addition, the axons of all four kitten Y-cells innervated the perigeniculate nucleus (PGN) as illustrated by the arrow in Fig. 1*j*. This type of axon collateral is quite common for adult Y-cells[10]. The somata of the kitten Y-cells that show this early physiological maturation are all in the lower end of the adult Y-cell size range (Fig. 2, range = 290–380 μm^2 in kitten and 285–750 μm^2 in adult). In summary, there is a population of Y-cells in the LGN$_d$ of 3–4-week old kittens that has mature physiological properties (nonlinear spatial summation within their receptive fields, consistent responses to repeated presentations of stationary visual targets, and responsiveness to targets moved rapidly through their receptive fields). These cells are also structurally very similar to adult Y-cells (relatively large somata, thick radially arranged dendrites, dendrites that cross laminar boundaries and innervation of the perigeniculate nucleus).

Until recently little was known about the postnatal maturation of the structure of LGN$_d$ A-laminae cells[21,22] and nothing of the development of the cells in the C-laminae. The data presented in this report support the hypothesis of differential morphological development of the functional subgroups of LGN$_d$ neurones. A population of Y-cells matures by 3–4 postnatal weeks while X-like cells are later to mature. In previous electrophysiological studies of kitten LGN$_d$ cells[20] and retinal ganglion cells[23,24] a definitive property of adult Y-cells (nonlinearity of spatial summation) was observed infrequently. This observation along with the reported greater sensitivity of the Y-system to the effects of monocular visual deprivation[12–18] during development suggests that the Y-cells are late to mature. It was therefore surprising to find that as a group the Y-cells of the kitten were more structurally mature than the X-like cells. However, other Y-cells may still mature later. At least two possible mechanisms could explain this. Some Y-cells may be so immature as not to generate action potentials and would be missed by the micropipettes. Alternatively, some of the X-like cells in the kitten may develop into Y-cells later. The neural circuitry of the retina which contributes the nonlinear subunits[5] may not be mature yet. An LGN$_d$ Y-cell that is innervated by such a retinal Y-cell would respond to a modulated grating pattern in a linear fashion and would be physiologically classified as an X-cell in the kitten. Since the results of other physiological tests used such as latency to optic chaism stimulation overlap in the kitten, such a cell can only be classified as X-like. The possibility that the LGN$_d$ Y-cell population may be further subdivided into groups that mature at different rates is further supported by studies of monocular visual deprivation[12–18]. These studies have all found that some normally responsive Y-cells develop in the LGN$_d$ laminae innervated by the visually deprived eye. However, fewer of these normal Y-cells occur in deprived laminae versus normal laminae. Other Y-cells develop abnormal structure and function after monocular visual deprivation[17]. The early maturing (structurally and functionally) Y-cells described in the present study may represent those normal Y-cells found in the adult that are resistant to the effects of visual deprivation.

The early morphological development of the W-cells in the C-laminae includes somatic growth (Fig. 2) as well as dendritic structure (Fig. 1*b*, *c*). This contrasts with the case in the A-laminae where somatic growth continues until 5–6 postnatal weeks of age[25–27]. If the soma size of the LGN$_d$ neurones relates to the size of their axonal arborization in visual cortex[28,29], the W-cells may thus have a relatively larger sphere of influence in the young kitten's cortex than X- and Y-cells. Along with the early physiological maturity of movement sensitive W-cells, this would suggest that the W-pathway may have an important role in visual processing in the young animal.

The variable rates of physiological maturation of neonatal LGN$_d$ cells are likely to depend on the development of the retinal ganglion cells that innervate them. However, the structural development of the LGN$_d$ cells may depend on intrinsic factors as well as retinal input.

I thank Loretta Hawkins for her technical assistance and USPHS grant EY 03805 for supporting this work, also Eldon Geisert, Terry Hickey and Mike Loop for helpful comments on the manuscript and Charlotte Shaw for typing the manuscript.

Monocular deprivation affects X- and Y-cell retinogeniculate terminations in cats

Mriganka Sur, Allen L. Humphrey & S. Murray Sherman

Department of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, New York 11794, USA

The X- and Y-cell pathways in cats form two functionally distinct, parallel systems from the retina through the lateral geniculate nucleus (LGN) to the visual cortex[1–4]. We recently used the technique of intraaxonal injection of horseradish peroxidase (HRP) to demonstrate major differences between X- and Y-cells in their retinogeniculate termination patterns[5] (compare Figs 1*a* and 2*a*). Normally, axons of X-cells innervate geniculate lamina A or A1 (depending on the eye of origin) in narrow zones oriented perpendicular to the lamination. Some X-cells also terminate sparsely (that is, with few boutons) in the medial interlaminar nucleus (MIN), a subdivision of the LGN. Y-cell axons terminate either in laminae C and A (from the contralateral retina) or in lamina A1 (from the ipsilateral retina) in broad zones[5,6], and most also terminate densely (with many boutons) in the MIN. We now report that cats raised with monocular lid suture develop abnormal retinogeniculate termination patterns. Many X-cell axons arising from the deprived eye have unusually broad terminal fields in lamina A or A1, and some also densely innervate the MIN. Many Y-cell axons from the deprived eye have dramatically shrunken or absent terminal fields in the A laminae and MIN. These changes constitute the most peripheral effects of monocular deprivation discovered so far, are consistent with previous reports of functional abnormalities among deprived geniculate neurones[4,7,8] and suggest possible mechanisms by which the visual environment influences neuronal development.

Previously described methods[5,9,10] were used to obtain results from nine adult cats (>8 months old) raised with continuous monocular deprivation from the first postnatal week. Briefly, recording micropipettes filled with 3% HRP, 0.2 M KCl and 0.05 M Tris were bevelled to 90–120 MΩ. An optic tract axon was first recorded extracellularly and identified as X or Y by standard criteria[10,11], including axonal conduction velocity (derived from response latency to electrical stimulation of the optic chiasm) and linearity of spatial summation to visual stimuli (measured by responses to counterphased, sine-wave gratings). Each axon was then impaled, its identity as X or Y was verified intracellularly, and HRP was iontophoresed into it[5,9]. After sufficient survival time, the brain was sectioned coronally at 100 μm and reacted with 3-3′-diaminobenzidine plus cobalt chloride[12]. The retinas in four animals were dissected free, flat-mounted on slides and reacted with *o*-dianisidine[13].

We successfully injected and recovered 9 X- and 11 Y-cell axons from deprived retinas and 11 X- and 7 Y-cell axons from nondeprived retinas. Axonal morphology in lid-sutured animals was also compared with that of 16 X- and 11 Y-cell axons recovered from normal, adult cats[5]. All axons from the nondeprived eye appeared identical in their termination patterns to axons in normal cats. Among the deprived axons, however, 4 X-cells and 8 Y-cells developed abnormal morphology. Nonetheless, we found no obvious physiological differences between deprived and nondeprived axons.

Monocular deprivation increases the density (number of boutons) and extent of many X-cell terminal fields. Figure 1 illustrates two X-cell axons from the deprived eye. The terminal field in Fig. 1*a* has apparently normal morphology, being restricted to a narrow zone in lamina A1. As in other normal axons, a thin medialward branch enters the brachium of the superior colliculus but could not be traced to any terminal zone. In contrast, a representative example of a morphologically abnormal X-cell terminal arbor is shown in Fig. 1*b*. The axon exhibits an abnormally wide terminal field in lamina A1, and it also has many more terminals in the MIN than any normal

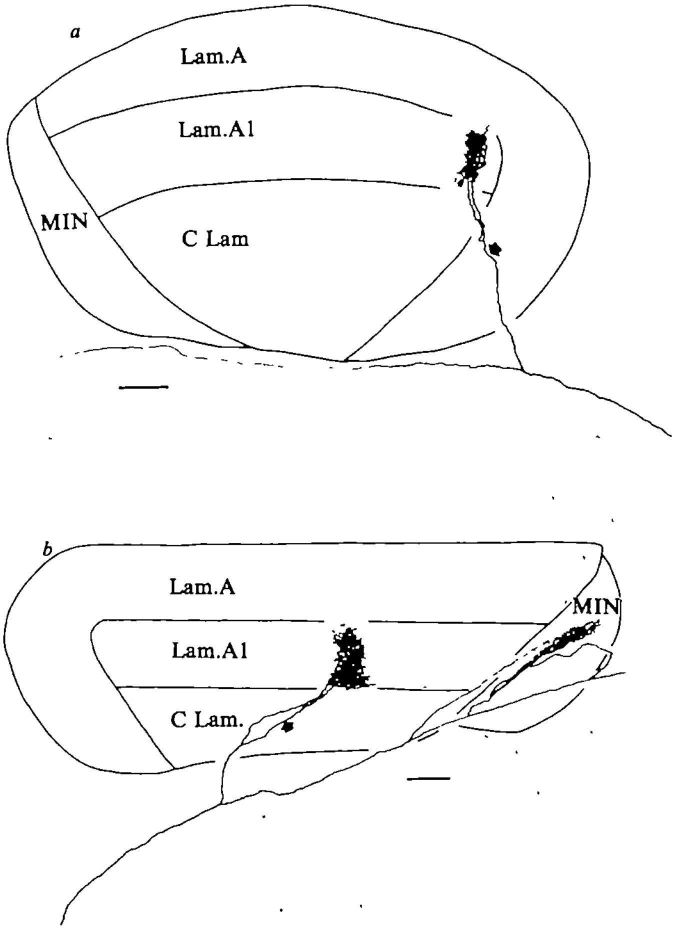

Fig. 1 Geniculate terminal zones of X-cell axons from the deprived eye Terminal zones of these X- and Y-cell axons were circularly symmetrical in the horizontal plane, and did not show obvious variations in size that could be related to eccentricity or type of centre response (that is, ON or OFF). *a*, Axon from the ipsilateral eye with apparently normal terminal pattern for an X-cell. This axon has 788 terminal boutons in lamina A1, which is within the range of 500–900 boutons for normal X-cell axons in lamina A or A1 Its receptive field was ON centre, had a centre diameter of 1.0°, and was located 44° from the vertical meridian and 23° below the zero horizontal parallel The axon's conduction latency from the optic chiasm to the recording and injection site (arrow) was 0 8 ms. The axon and its terminal field were reconstructed from 21 serial, 100-μm thick, coronal sections. Scale bar, 250 μm. *b*, Axon from the ipsilateral eye with abnormal terminal pattern. The extent of terminal field in either lamina A1 or the MIN exceeds any seen for normal or nondeprived X-cells. Thus, this axon has 1,077 terminal boutons in lamina A1 and 175 boutons in the MIN (compared with 7–31 boutons for normal X-cell axons that innervate the MIN). This axon's receptive field was OFF centre, had a centre diameter of 0 6°, and was located 11° from the vertical meridian and 3° below the horizontal zero parallel. Its conduction latency from the optic chiasm to the recording and injection site (arrow) was 0.7 ms. The axon and its terminal field were reconstructed from 17 serial, 100-μm thick, coronal sections. Scale bar, 250 μm.

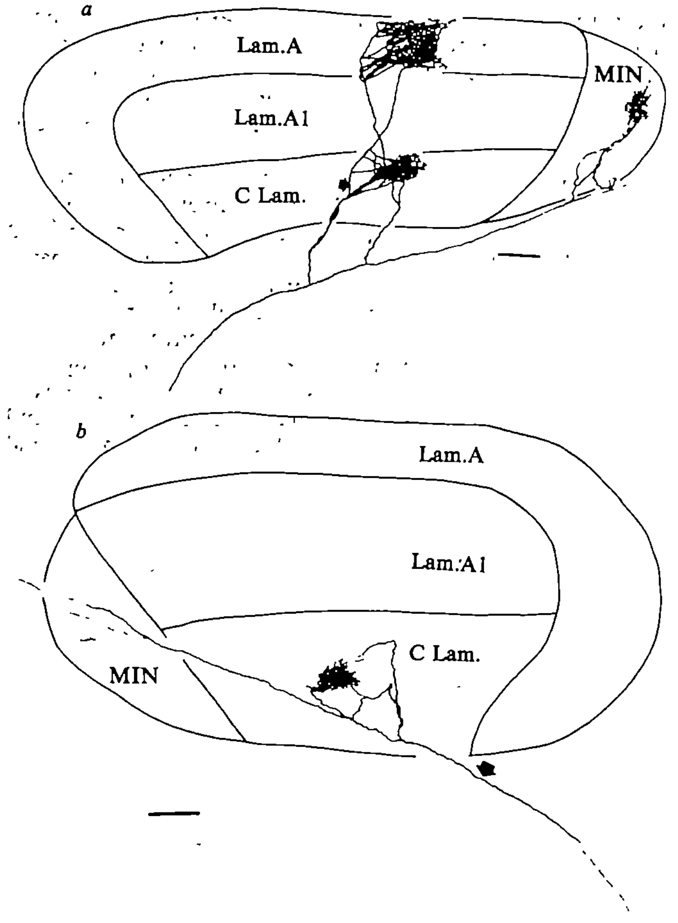

Fig. 2 Geniculate terminal zones of Y-cell axons from the deprived eye. *a*, Axon from the contralateral eye with apparently normal termination pattern for a Y-cell. This axon has 683 terminal boutons in lamina A (the range for normal Y-cell axons in lamina A or A1 is 650–1,400 boutons) and 121 terminal boutons in the MIN (normal range 90–170 boutons). Its receptive field was OFF centre, had a centre diameter of 1.3°, and was located 4° from the vertical meridian and 7° below the zero horizontal parallel. The axonal conduction latency from the optic chiasm to the recording and injection site (arrow) was 0.5 ms. The axon and its terminal field were reconstructed from 19 serial, 100-μm thick, coronal sections. Scale bar, 250 μm. *b*, Axon from the contralateral eye with abnormal terminal pattern. The axon terminates densely only in the C-laminae, has no terminal boutons in the A-laminae and sparsely innervates the MIN with only 6 boutons. This contrasts sharply with the normal pattern described in the text. This axon's receptive field was OFF centre, had a centre diameter of 1.6°, and was located 7° from the vertical meridian and 40° below the zero horizontal parallel. Its axonal conduction latency from the optic chiasm to the recording and injection site (arrow) was 0.4 ms. The axon and terminal field were reconstructed from 18 serial, 100-μm thick, coronal sections. Scale bar, 250 μm.

X-cell axon seen to date. Figure 3 summarizes some of these phenomena for arbors in the A-laminae.

Monocular deprivation affects Y-cells even more dramatically than it does X-cells, but in a different way. Figure 2*a* shows a normal Y-cell terminal field from the deprived retina. The axon terminates densely in laminae A and C, plus the MIN. In contrast, Fig. 2*b* illustrates an example of a deprived Y-cell axon that terminates densely in the C-laminae, sparsely in the MIN and not at all in the A-laminae. In normal cats, every Y-cell axon found terminates densely in lamina A or A1, and the majority that terminate in the MIN do so densely there[5,6]. Of six deprived Y-cell axons from the contralateral eye, four innervate only the C-laminae and do not terminate in lamina A. Four additional deprived Y-cell axons (one contralateral, three ipsilateral) have terminal fields in the A-laminae that are narrower and with fewer boutons than normal. Thus, deprived Y-cell terminals are most affected in the binocular segment of the A-laminae (Fig. 3), less so in the MIN, and seem normal in the C-laminae. The clearest effect of monocular lid suture on retinogeniculate Y-cell terminations, however, is that many contralateral Y-cell axons innervate only the C-laminae and do not innervate lamina A. If these four axons that fail to innervate lamina A are removed from the comparison in Fig. 3, the remaining Y-cell terminal fields are only marginally smaller than those of the normal and nondeprived Y-cells. More data are needed to determine whether the effects of deprivation are continuous such that some Y-cell terminal zones in the A-laminae are missing, some smaller than normal, and some normal, or whether the effects cause complete elimination of some Y-cell terminal fields with no effect on others.

We are confident that the abnormally small terminal fields seen in many deprived Y-cell axons are not due to incomplete or poor staining. These axons were darkly stained, as were the nondeprived and normal axons, and each axonal branch could be traced to a terminal bouton. Also, the same tissue often included axons with normal and abnormal morphology.

Figure 4 shows the retrograde labelling obtained for the somata of two identified axons that were filled with HRP. Such labelling was obtained for four X- and four Y-cells in deprived retinas and three X- and five Y-cells in nondeprived retinas. X-cell somata were consistently smaller than Y-cell somata[14], but no obvious size differences could be seen between the deprived and nondeprived somata despite large changes in the terminal field extents of the former. However, such comparisons are complicated by differences in retinal eccentricity[15,16].

Many studies have established that monocular deprivation causes abnormalities to develop in the cat's central visual pathways[4]. The expanded X-cell and reduced or absent Y-cell retinogeniculate projections described here constitute the most peripheral morphological effects of deprivation seen so far. Furthermore, although our study seems inconsistent with a recent ultrastructural study[17] that reported normal numbers and structure for retinal synapses in the deprived A-laminae,

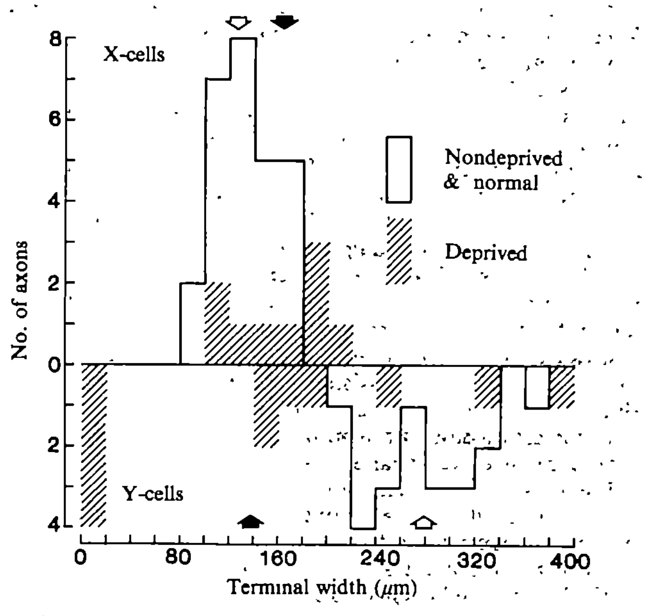

Fig. 3 Maximum widths of terminal zones in the A-laminae for X- and Y-cell axons with receptive fields in the binocular segment. The widths were measured along a plane parallel to the lamination. Because this is the plane of circular symmetry for these terminal fields and there is no effect of eccentricity or centre type on their size (see Fig. 1 legend), it seems unlikely that differences in terminal field widths result from histological artefacts. Data for nondeprived axons and axons from normally reared cats were pooled, as they are morphologically indistinguishable. Open arrows denote mean widths for normal and nondeprived axons; closed arrows, for deprived axons. Terminal zones for deprived X-cell axons are larger than those for nondeprived or normal X-cell axons ($P < 0.05$ on a Mann–Whitney *U*-test for either comparison). These zones for deprived Y-cell axons are smaller than are those for nondeprived or normal Y-cell axons ($P < 0.01$ on a Mann–Whitney *U*-test for either comparison). However, if the four contralateral Y-cell axons that do not innervate lamina A are omitted from the comparison, the difference between deprived and nondeprived or normal Y-cell terminal widths in the A-laminae is less significant ($0.05 < P < 0.1$ on a Mann–Whitney *U*-test).

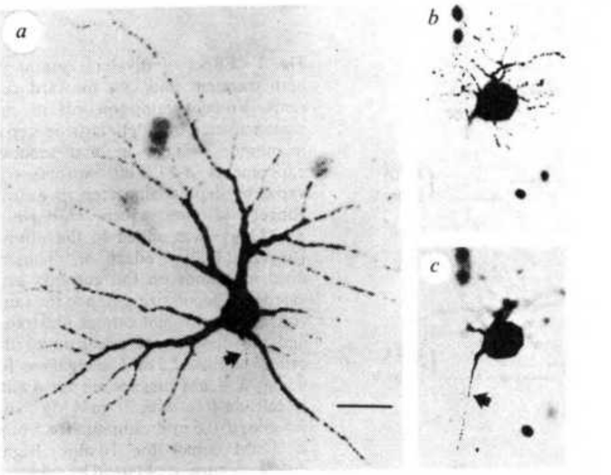

Fig. 4 Photomicrographs of retinal ganglion cells labelled retrogradely following HRP injection into their axons. Each ganglion cell was identified unambiguously by comparing its location relative to retinal blood vessels with plots of the vessels and receptive field made during the recording. *a*, Y-cell in nondeprived retina. The neurone's receptive field was OFF centre, had a centre diameter of 2.6°, and was located 17° from the vertical meridian and 45° below the zero horizontal parallel. The morphology of this Y-cell is characteristic of α cells[14-16]. The arrow points to the axon. Scale bar, 50 μm and applies as well to *b* and *c*. *b*, *c*, Two focal planes of same field of view showing an X-cell in nondeprived retina. The neurone's receptive field was OFF centre, had a centre diameter of 0.9°, and was located 20° from the vertical meridian and 5° below the zero horizontal parallel. The morphology of this X-cell is characteristic of β cells[14-16]. The focus is adjusted for the dendrites in *b* and for the soma and axon (arrow) in *c*.

the two sets of data may actually be compatible. Prior evidence suggests that retinal X-cells outnumber Y-cells by roughly 10 to 1 (refs 15, 16). Even with roughly twice as many boutons from Y-cell axons as from X-cell axons[5], retinogeniculate synapses in the A-laminae arising from X-cells probably outnumber substantially those from Y-cells. It is impossible to distinguish between X- and Y-cell retinogeniculate synapses in conventional ultrastructural material[18]. Thus, if one were to study these synapses in deprived laminae without knowledge of X- and Y-cell identity, a fairly substantial loss of terminals from the less numerous Y-cell axons with a slight expansion of terminals from more numerous X-cell axons might result in ultrastructure that appeared fairly normal. On the other hand, our data are consistent with both the loss of recorded geniculate Y-cells from deprived laminae[7] and the finding that many deprived geniculate neurones that normally accept only Y-cell input from the retina accept or retain X-cell input instead[8].

The abnormal terminal arbors we have described suggest that deprivation might cause retinogeniculate X-cell connections to expand at the expense of Y-cell connections by some sort of competitive interaction during development. X-cell axons normally seem to innervate the lateral geniculate nucleus before Y-cell axons do[19,20]. Perhaps, as in many developing pathways[21-23], the immature X-cell pathway is exuberant and is 'pruned back' in competitive interactions with the later-developing Y-cell inputs. The ability of Y-cell axons to dislodge the already-present X-cell axons may be severely reduced during visual deprivation. Consistent with this hypothesis is our observation that deprived Y-cell terminals are most severely affected in the A-laminae, where geniculate X-cells are concentrated. One means of testing this hypothesis would be to study the termination patterns of X- and Y-cell retinogeniculate axons in developing kittens.

Regardless of the developmental mechanisms, our evidence clearly shows that the visual environment can influence the formation of retinogeniculate terminations. Early visual deprivation causes abnormalities in these connections, which most seriously affect the Y-cell pathway. This might well represent the neural basis of amblyopia seen in monocularly deprived cats, as the Y-cell pathway may have a crucial role in normal vision[24].

Action potential repolarization may involve a transient, Ca^{2+}-sensitive outward current in a vertebrate neurone

Amy B. MacDermott & Forrest F. Weight

Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, 12501 Washington Avenue, Rockville, Maryland 20852, USA

Repolarization of the action potential in squid axon[1] and several types of neurones[2-4] involves a voltage-activated potassium (K^+) current. Voltage clamp analysis has demonstrated that this current has rapid activation kinetics[1,3-5]. In several neuronal types, the same technique has also revealed a slowly activated K^+ current that is calcium (Ca^{2+})-sensitive[3,5-10]. This slow Ca^{2+}-activated K^+ current is the major current underlying the late, slower portion of the after-hyperpolarization following an action potential[11-14]. In several muscle types, fast, transient Ca^{2+}-dependent K^+ currents have been described[15-17] which may contribute to repolarization of the action potential. Rapidly activating, Ca^{2+}-dependent K^+ currents have been observed in sympathetic neurones of the bullfrog and it has been suggested that they contribute to action potential repolarization of those neurones[8,9,18]. We have studied the membrane currents in bullfrog sympathetic neurones using voltage clamp methods and report here a transient outward current that appears to be composed of two separate currents. One of those currents is a transient, Ca^{2+}-sensitive outward current as indicated by a significant reduction of the current by treatments that reduce or block Ca^{2+} entry (Mn^{2+}, Cd^{2+}, Co^{2+}, Mg^{2+} or Ca^{2+}-free Ringer). Such treatments also decreased the rate of action potential repolarization. The results suggest that this current is involved in repolarization of the action potential and consequently may regulate Ca^{2+} entry into the neurone during spike activity.

The IXth and Xth paravertebral sympathetic ganglia of bullfrog (*Rana catesbeiana*) were excised, pinned in a Plexiglass recording chamber and continuously superfused with a Ringer's solution of the following composition (mM): NaCl 117; KCl 2.5; $CaCl_2$ 1.8; HEPES 1 (pH 7.3). Most preparations were

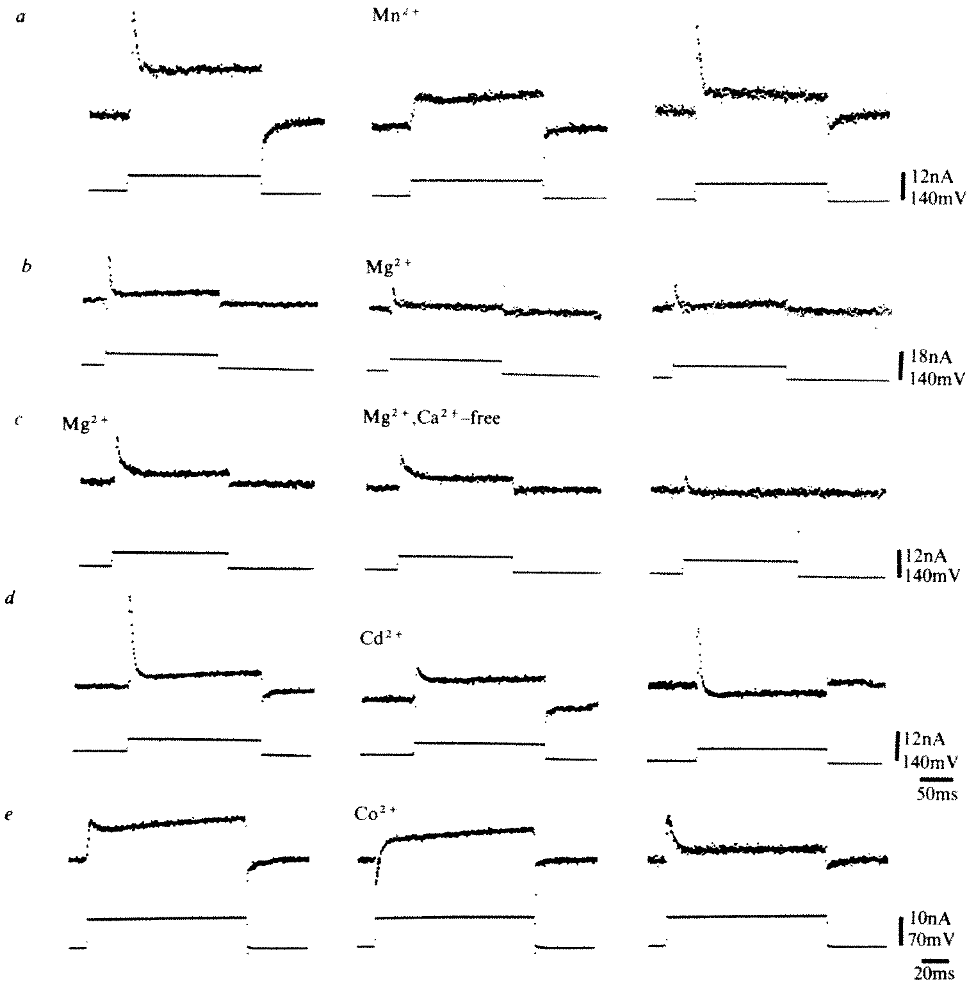

Fig. 1 Effect of divalent cations on both transient and late outward currents. Voltage-clamp records of currents activated by a depolarizing step of membrane voltage in five separate experiments (*a–e*). Left: currents activated by depolarizing step in normal Ringer's solution, except *c* in which 8 mM Mg^{2+} was added to the normal Ringer. Middle: effect of changing divalent cations on the currents activated by a depolarizing step to the same voltage; the divalent cations illustrated and the duration of exposure to the cations are: *a*, 2.5 mM manganese for 9 min; *b*, 8 mM magnesium for 4 min; *c*, calcium-free with 10 mM Mg^{2+} for 6.5 min; *d*, 0.5 mM cadmium for 5 min; *e*, 3 mM cobalt for 16 min. Right: difference current obtained by subtracting the currents recorded with altered divalent cations (middle) from control currents in normal Ringer (left). In the difference record in *d*, the inward current that follows the transient outward current resulted from an increased leak current which occurred in Cd^{2+}. An increased leak was not observed in the presence of the other divalent cations. In *a–e* the depolarizing step was to −15 mV. The holding potentials were: *a*, −92 mV; *b*, −82 mV; *c*, −78 mV; *d*, −80 mV; *e*, −85 mV. Experiments were conducted using the two-microelectrode voltage-clamp technique, as described previously[19]. The records are from data stored by a PDP 11/03 microcomputer. The current signal was filtered for frequencies above 1 or 3 kHz, which is similar to the settling time of the clamp; therefore the peak amplitude of fast current may be underestimated.

treated with 1.0% trypsin for 5–7 min followed by a 10-min exposure to trypsin inhibitor before final desheathing of the ganglion. Large neurones (>50 μm) were selected for impalement. Microelectrodes were filled with 3 M KCl and had an electrical resistance of 25–40 MΩ. Two microelectrodes were used for voltage-clamp experiments as described previously[19]; a single microelectrode was used for recording the action potential.

Both the early and late currents activated by depolarizing steps of membrane voltage and the effect of various treatments that reduce Ca^{2+} entry on those currents are illustrated in Fig. 1. The records on the left in Fig. 1 show the currents activated by depolarizing voltage steps in five different experiments (*a–e*). At the initiation of the voltage step there was a quickly activating, transient outward current that decayed rapidly. It was followed by a slow outward current that has been described previously[7–10]. The middle records illustrate the effect of 2.5 mM manganese (*a*), 8 mM magnesium (*b*), Ca^{2+}-free Ringer (*c*), 0.5 mM cadmium (*d*) and 3 mM cobalt (*e*). The transient outward current was significantly reduced by each of these treatments. The records on the right are the difference currents, which were obtained by subtracting the currents recorded in the altered divalent cation Ringer (middle) from the currents recorded in normal Ringer's solution (left). The right-hand records thus show the currents that were sensitive to either the addition of a Ca^{2+} blocking divalent cation or the omission of Ca^{2+} from the Ringer's solution.

Figure 2 shows the transient outward current recorded at a rapid sampling rate. Voltage control of the soma was achieved before the current reached peak amplitude. The development of this current with a depolarizing voltage step from −59 to −21 mV is shown in Fig. 2*a*. Following the return of membrane potential to −49 mV, a fast outward tail can be observed. In Fig. 2*b*, an inward current is seen before the transient outward current. Figure 2*c* shows two pairs of currents recorded from the same cell before and during exposure to 3 mM Co^{2+}. In normal Ringer (Fig. 2*c*i), the transient outward current developed quickly with the peak amplitude depending on the holding potential (−76 and −104 mV). In the Ringer containing Co^{2+} (Fig. 2*c*ii), an inward current was revealed followed by a more slowly developing, but early, outward current. The divalent cation-sensitive component of the transient outward current was a labile current. It seemed to be present only in cells that had resting potentials > −40 mV and spike amplitudes >80 mV following impalement with two electrodes. The amplitude of the transient outward current declined slowly with time under clamp, making recovery from a divalent cation block difficult to demonstrate. We have, however, observed recovery of both the transient and slow outward currents following exposure to Mg^{2+}, which washes out relatively quickly.

Figure 3 illustrates the effect of membrane holding potential on the activation of the transient outward current. Figure 3*a*i shows examples of the currents activated in normal Ringer's solution from membrane holding potentials from left to right of −28, −37, −55 and −92 mV. Figure 3*b* is a graph of the amplitude of the transient outward current as a function of membrane holding potential. In normal Ringer's solution, the current was activated over the range of holding potentials tested, from −105 mV to −23 mV. The amplitude of this transient current decreased as membrane holding potential was made more positive, suggesting a voltage-dependent inactivation process. The strong dependence of the transient current on holding voltage is not characteristic of the slower, 'steady-state' currents. In most cells there was a decrease in the slope of the inactivation curve at membrane holding potentials near both −60 mV and −90 mV (Fig. 3*b*). The currents activated

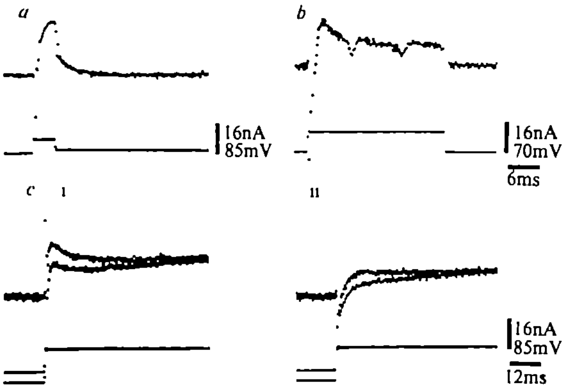

Fig. 2 Transient outward current recorded at a rapid sampling rate. *a*, Transient outward current activated by a voltage step from −59 to −21 mV. Shortly after the current peaked, membrane potential was stepped to −49 mV; this was accompanied by an outward tail current (filtered at 1 kHz). *b*, Response of a different cell clamped at −59 mV and stepped to −15 mV (filtered at 10 kHz). In this case, the transient outward current was preceded by an inward current. The two inward current events riding on the decaying outward current are presumably from axonal spikes. *c*, Current records from the same cell before (ci) and during (cii) exposure to a Ringer's solution containing 3 mM Co^{2+}. The membrane was voltage clamped at holding potentials of −76 and −104 mV and stepped to −15 mV to activate the outward current. Filtering frequency was 3 kHz.

from the same series of membrane holding potentials in the presence of 2.5 mM Mn^{2+} are shown in Fig. 3*a*ii. The amplitude of the transient current in the presence of Mn^{2+} is plotted in Fig. 3*b*. In the Mn^{2+} containing Ringer, a transient outward current was only apparent at membrane holding potentials negative to −60 mV. In addition, the shape of the inactivation curve in Mn^{2+} differed from the curve in normal Ringer, with a single, smooth rising phase between −60 and −80 mV and a distinct flattening at more negative potentials. The voltage-dependent inactivation characteristics of this transient outward current are similar to those of the A-current, first identified in molluscan neurones[20]. Similar results were obtained with Ringer's solutions containing 0.5 mM Cd^{2+}, 3.0 mM Co^{2+}, and with Ca^{2+}-free Ringer. Figure 3*a*ii also shows that in the presence of 2.5 mM Mn^{2+}, an early inward current was revealed as in Fig. 2*c*ii. This inward current accounts for the apparent reversal of the transient outward current in Fig. 3*b*. The inward current was partially blocked by 10^{-5} M tetrodotoxin (not shown) and is presumably a Na^+ current.

The effect on action potential repolarization of treatments that reduce Ca^{2+} entry are illustrated in Fig. 4. In the presence of a Ringer's solution containing 3 mM Mn^{2+}, the rate of action potential repolarization was slowed, resulting in an increased spike duration (Fig. 4*a*, upper traces). In addition, the amplitude of the after-hyperpolarization following the action potential was reduced. These changes can be seen more clearly in the electronically differentiated records (lower traces). Figure 3*b* shows the effect of a Ca^{2+}-free Ringer on the generation of the action potential. In these records, successive traces were superimposed during both the wash-in and the wash-out of the Ca^{2+}-free Ringer, showing clearly both the decreased rate of action potential repolarization and the reduction of the after-hyperpolarization. Similar effects were also observed with 0.5 mM Cd^{2+}.

The reduction of the transient outward current by a Ca^{2+}-free Ringer indicates that at least part of the current is Ca^{2+}-sensitive. The similar effect of Mn^{2+}, Cd^{2+}, Co^{2+} and Mg^{2+} suggests that these divalent cations suppress this Ca^{2+}-sensitive component of the transient current. The divalent cations used have been found to reduce or block the entry of Ca^{2+} in many cell types[21]. In bullfrog sympathetic neurones, Cd^{2+} has been shown to antagonize the Ca^{2+} current recorded in voltage-clamp experiments[10]. Moreover, in experiments using the Ca^{2+}-sensitive dye Arsenazo III to detect intracellular Ca^{2+} in these neurones[22], Mn^{2+} has been found to block the entry of Ca^{2+} resulting from a train of action potentials (S. J. Smith, A. B. MacD., and F.F.W., in preparation). The effect of membrane holding potential indicates that the Ca^{2+}-sensitive transient outward current has characteristics that differ significantly from the characteristics of the transient outward current recorded in the presence of Mn^{2+}, Cd^{2+}, Co^{2+} or Mg^{2+}, or with omission of Ca^{2+} from the Ringer's solution which suggests the presence of two separate currents. The presence of two, transient outward currents that both decay rapidly, one of which may be Ca^{2+}-dependent, has also been identified in cardiac Purkinje fibres[23].

A Ringer's solution containing 10 mM tetraethylammonium (TEA) or 5 mM Ba^{2+} blocks virtually all of the transient outward current[9]. TEA inhibits the voltage-activated or rectifier K^+ current[6,24] and can also block Ca^{2+}-sensitive K^+ currents[25–27]. Ba^{2+} has been found to block several K^+ currents in neurones including Ca^{2+}-sensitive[27,28], delayed rectifier[29,30], and M-currents[7,9,31]. Inhibition of the transient outward current in bullfrog sympathetic neurones by TEA or Ba^{2+} suggests that both the Ca^{2+}-sensitive transient outward current and the transient outward current that is not Ca^{2+}-sensitive are carried by K^+. Further evidence that they are carried by K^+ is the observation that the amplitude of the transient outward current decreased in a Ringer containing 25 mM KCl. Similar fast K^+

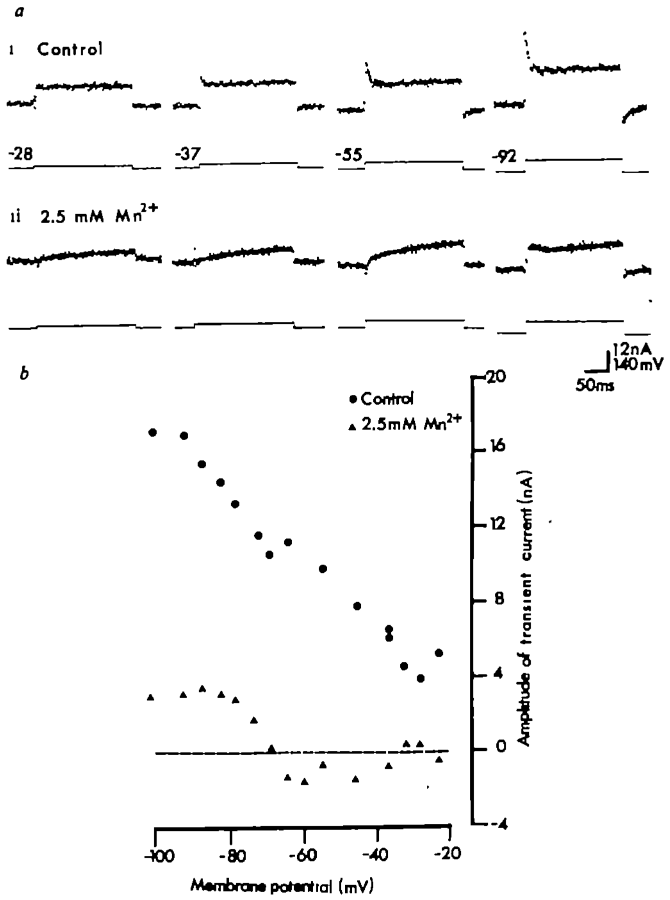

Fig. 3 Effect of membrane potential on amplitude of the transient outward current. *a*, Membrane voltage was held at a given potential for 8 s, stepped to an activation voltage of −15 mV for 200 ms, then returned to a new, more negative holding potential. (Paired pulse experiments showed that holding at a negative holding potential for more than 500 ms was necessary for recovery from inactivation.) *a*i, Effect of membrane potential on currents activated by a depolarizing step to −15 mV in normal Ringer's solution; the membrane holding voltage before each step is labelled on the voltage trace. *a*ii, Effect of 2.5 mM Mn^{2+} on outward currents activated by the same depolarizing steps from the same holding potentials in the same cell as *a*i. *b*, Graph of relationship between amplitude of the transient outward current (nA) and membrane holding potential (mV) before depolarizing step to −15 mV in normal Ringer (●) and a Ringer containing 2.5 mM Mn^{2+} (▲). Amplitude of the transient outward current was measured as the difference between the transient outward current peak and the baseline current, minus the leak current. Leak current was calculated by dividing the voltage difference of the step by the slope resistance between −65 and −90 mV. Experiments conducted using two microelectrode voltage-clamp technique[19].

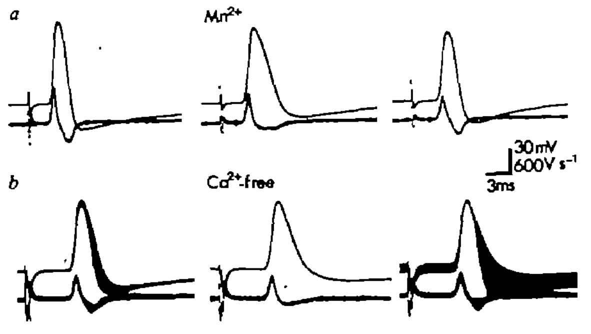

Fig. 4 Effect of divalent cations on action potential repolarization *a*, Effect of 3 mM Mn^{2+} on the action potential. Left· action potential recorded in normal Ringer's solution. Middle· action potential recorded after superfusion for 6 min with Ringer containing 3 mM Mn^{2+}. Right: action potential recorded 13 min after beginning Mn^{2+} wash-out Top trace: voltage recording of action potential. Bottom trace: electronically differentiated record of action potential. Since the addition of Mn^{2+} depolarized the cell, the membrane potential was offset to the control resting potential (−55 mV in this cell) using a bridge circuit. *b*, Effect of Ca^{2+}-free Ringer containing 6 mM Mg^{2+} on the action potential. Left: superimposed action potentials recorded initially in normal Ringer and during wash-in with Ca^{2+}-free Ringer containing 6 mM Mg^{2+}. Middle: single action potential recorded after superfusion for 10 min with Ca^{2+}-free Ringer containing 6 mM Mg^{2+}. Right. superimposed action potentials during wash-out of the Ca^{2+}-free Ringer. The resting membrane potential of this cell was −60 mV. Top trace· voltage recording of action potential. Bottom trace: electronically differentiated record of action potential. Action potentials were elicited by antidromic stimulation of the IXth or Xth spinal nerves. Records were photographed from oscilloscope trace.

currents which appear to be Ca^{2+}-sensitive or partially Ca^{2+}-sensitive have been identified in cardiac Purkinje fibres[17,32], crab muscle[16] and guinea pig myometrium[15].

The transient outward current reported here seems to be different from another fast, Ca^{2+}-activated K^+ current observed in bullfrog sympathetic neurones. Adams *et al.*[18] recently described a fast, Ca^{2+}-activated, voltage-sensitive K^+ current with an activation time constant of about 15–20 ms. The various methods used to estimate the time constant in their study involved holding the membrane potential at −10 mV. The transient outward current studied in the experiments reported here also peaks rapidly, in less than 5 ms with pulses to −10 mV; however, it inactivates rapidly following activation and thus presumably does not contribute to the currents measured in the study of Adams *et al.* As the mechanisms underlying the different properties of these two currents are unclear, the relationship between these two Ca^{2+}-sensitive outward currents is a question for future investigation.

In cat motoneurone, a fast K^+ current has been studied which is blocked by Co^{2+}, Mn^{2+}, Ni^{2+} and TEA[33]. However, these treatments did not appreciably broaden the directly activated action potential. In contrast, a decreased rate of action potential repolarization was observed in bullfrog sympathetic neurones in Ca^{2+}-free Ringer or in the presence of Ca^{2+}-blocking divalent cations. This suggests that the Ca^{2+}-sensitive transient outward current contributes to repolarization of the action potential in these vertebrate neurones. It is also possible that this current may limit the entry of Ca^{2+} into the neurone during spike activity. Since a voltage-sensitive Ca^{2+} current is activated during membrane depolarization[10,22,34], an outward current that is rapidly activated by Ca^{2+} entry would rapidly repolarize the cell thus inhibiting further Ca^{2+} entry.

We thank Dr James Kenyon for his helpful comments on the manuscript, and Ms Melpi Jeffries and Ms Millie Wilkins for their help in preparing the manuscript.

Generation of mucosal mast cells is stimulated *in vitro* by factors derived from T cells of helminth-infected rats

The connective tissue of rats, and several other species of mammals, contains two distinct types of mast cells that differ in morphology, histochemical staining properties and location[1]. One type, frequently called the normal connective tissue mast cell, can be obtained in nearly homogeneous preparation from a mixed cell population in the peritoneal cavity and forms the basis of our knowledge of mast cells. The other type is referred to as the mucosal mast cell because in normal rats it has been observed only in mucosal tissue. Infection with helminth parasites induces an extensive accumulation of mast cells and eosinophils in the tissues[1,2], and parasites of mucous surfaces, in particular, stimulate a rapid hyperplasia of mucosal mast cells[3,4]. However, the origin of mucosal mast cells, and their relationship to the connective tissue mast cells is uncertain. We now show that lymphocytes of helminth-infected rats, on *in vitro* stimulation with specific antigen, release factors causing pronounced mucosal mastocytosis in normal rat bone marrow cultures.

Conditioned media capable of causing the proliferation of mast cells were derived from cultures of antigen-stimulated mesenteric lymph node cells of rats infected with the nematode *Nippostrongylus brasiliensis*. Figure 1 illustrates that the medium from such cultures added to normal rat bone marrow cultures encourages cell growth and enriches for mast cells. The conditioned medium also contains some growth stimulating activity for neutrophils, macrophages and eosinophils (not shown). However, restimulation and refeeding leads to cultures containing greater than 90% mast cells. By contrast, the culture

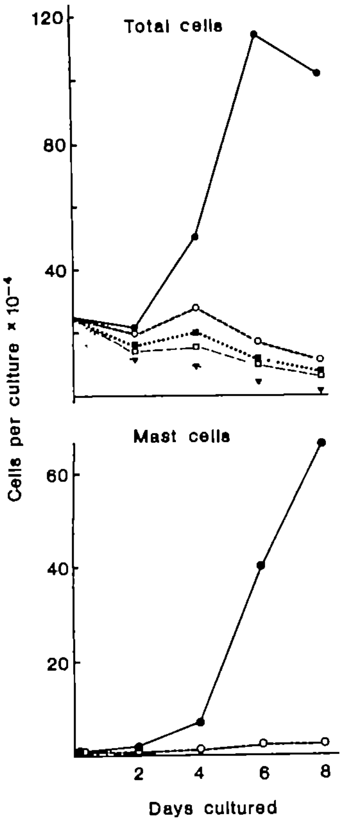

Fig. 1 Growth of bone marrow cells in the presence of culture fluids from antigen-stimulated mesenteric lymph node cells (MLN) of rats infected with *N. brasiliensis*. Shown above, in the upper section, total cells in bone marrow cultures (mean of 3) with added supernatant from: antigen-stimulated infected rat MLN (●); antigen-unstimulated infected rat MLN (○); antigen-stimulated (■) and unstimulated normal rat MLN (□); and unconditioned medium containing Nb antigen only (▼). In the lower section, mast cells in the first two of the above cultures. The bone marrow culture technique was adapted from the method of Sumner *et al.*[23]. Normal bone marrow cells from (LIS × BN) F$_1$ rats suspended at 2.5×10^5 ml^{-1} in Iscove's medium (Gibco) with 20% horse serum were cultured in 35 mm tissue culture dishes at 37 °C in a humidified incubator flushed with 5% CO$_2$ in air. Any effect of small amounts of endogenous growth stimulating activity is not detected at this low cell density: these cultures thus provide a simple system for the assay of exogenous growth stimulating activity. Twenty per cent conditioned medium, obtained by culturing syngeneic mesenteric lymph node cells from normal or infected rats in the presence of *N. brasiliensis* antigen, was added to the cultures. Rats were infected with 4,000 *N. brasiliensis* larvae[24] and mesenteric lymph nodes were removed between 12 and 30 days after infection. The lymph node cells were suspended at 4×10^6 ml^{-1} in Iscove's serum-free medium[25]. *N. brasiliensis* antigen was added at 10 μl ml^{-1}. The cells were incubated for 5 days as above and the supernatant was collected and filtered. For preparation of the antigen, adult worms were removed from the intestines of infected rats on the eighth day of infection, washed by sedimentation in 0.15 M saline and incubated in Hank's medium at 37 °C for 3 h. The supernatant containing antigenic secretions and excretions of the parasites was adjusted to a protein concentration of 1 mg ml^{-1} and filtered.

medium from antigen-stimulated normal rat mesenteric lymph node cells or from antigen-unstimulated infected or normal lymph node cells does not show these properties. The necessity to stimulate the infected rat cells with antigen to obtain conditioned medium with optimal activity indicates that primed antigen-specific cells must be activated.

Cell separation experiments indicated that the mast cell growth factor is produced by immunoglobulin-negative non-adherent cells. Thus infected rat lymph node cells depleted of plastic-adherent and immunoglobulin-bearing cells yield a culture fluid of undiminished conditioning activity whereas the supernatant fluids of cultured adherent or immunoglobulin-bearing cells have little effect. These preliminary experiments suggest, therefore, that mast cell growth factor is produced by antigen-specific T cells contained within the draining lymph nodes of *N. brasiliensis*-infected rats. This conclusion is reinforced by previous observations that the proliferation of mucosal mast cells in helminth infections is dependent on the integrity of the T lymphocyte system of the host[5–7] and can be adoptively transferred by immune T cells[8]. Although there has been controversy on this point the evidence now indicates that T cells have an inductive rather than a precursor role in influencing mucosal mast cell numbers[7].

It is often difficult to distinguish mucosal from connective tissue populations of mast cells as both possess specific receptors for IgE and dense secretory granules containing proteoglycan, histamine and basic proteins. However, mucosal mast cells require special fixation techniques for their detection in tissues and differ from connective tissue mast cells in having granules which are sparser and more variable in size and which contain less strongly sulphated glycosaminoglycans and less monoamine[9]. Additionally, each type of mast cell contains a similar yet antigenically distinct chymotrypsin-like serine protease which can be used to define the type of mast cell present in any preparation[10,11].

The mast cells generated in our cultures have the following properties. Morphologically they differ from peritoneal mast cells in being smaller and having sparser granules which show a marked variation in size (Fig. 2). Following fixation of cytocentrifuge preparations in Carnoy's fluid and staining by the astra blue (*p*H 0.3)/safranin technique, the granules of the cultured mast cells stained exclusively with astra blue whereas, by comparison, those of peritoneal mast cells stained exclusively with safranin. Preparations fixed in Carnoy's fluid and stained with toluidine blue (*p*H 0.5) were metachromatic. Uptake of IgE by surface receptors of cultured mast cells was demonstrated by overnight incubation with monoclonal rat IgE (IR162) or with serum rich in IgE from *N. brasiliensis* immune rats[12] followed by a 1-h incubation in FITC-labelled purified goat anti-rat Fcε. Finally, extracts of the cultured mast cells contained a very high level of mucosal mast cell protease (26 μg per 10^6 mast cells) (Fig. 3).

Others have observed mast cell proliferation in cultures of various tissues grown in media conditioned by antigen-stimulated[13,14] or concanavalin A-stimulated lymphocytes[15–17]. In these studies the type of mast cell was not ascertained. Ginsburg and colleagues, however, have recently identified two types of mast cells in cultures of mouse lymphoid tissue grown on an embryonic fibroblast monolayer: one type, the proliferation of which was dependent on the presence of antigen-specific T cells or their products, arose from a precursor in the lymphoid cell layer; the other type, not dependent on T-cell factors, arose from cells in the fibroblast layer[18]. Although critical discriminating tests were not performed, it was suggested that the lymphoid-derived cells were mucosal mast cells and the feeder layer-derived cells were connective tissue mast cells. As the greatest differentiation and proliferation of 'mucosal' mast cells occurred with mesenteric lymph node cells and few arose from bone marrow cells[19], it was proposed that the 'mucosal' mast cell derived from a precursor in lymphoid tissue[18].

Our present results suggest that the precursor cell for the mucosal mast cells, like the precursor for the connective tissue population[20], originates in the bone marrow. The same conclusion has recently been reached independently by Crowle[21] based on *in vivo* experiments with W/W^v mice. We propose that *in vivo* the precursor cell, after migrating from the bone marrow, would normally differentiate *in situ* in the areas where both the antigen and antigen-specific T cells are to be found—a proposition supported by ultrastructural observations of infected tissues[22]. It should now be possible to analyse the signals and the steps involved in mast cell proliferation in a system which reflects and is directly relevant to the mastocytosis occurring *in vivo*.

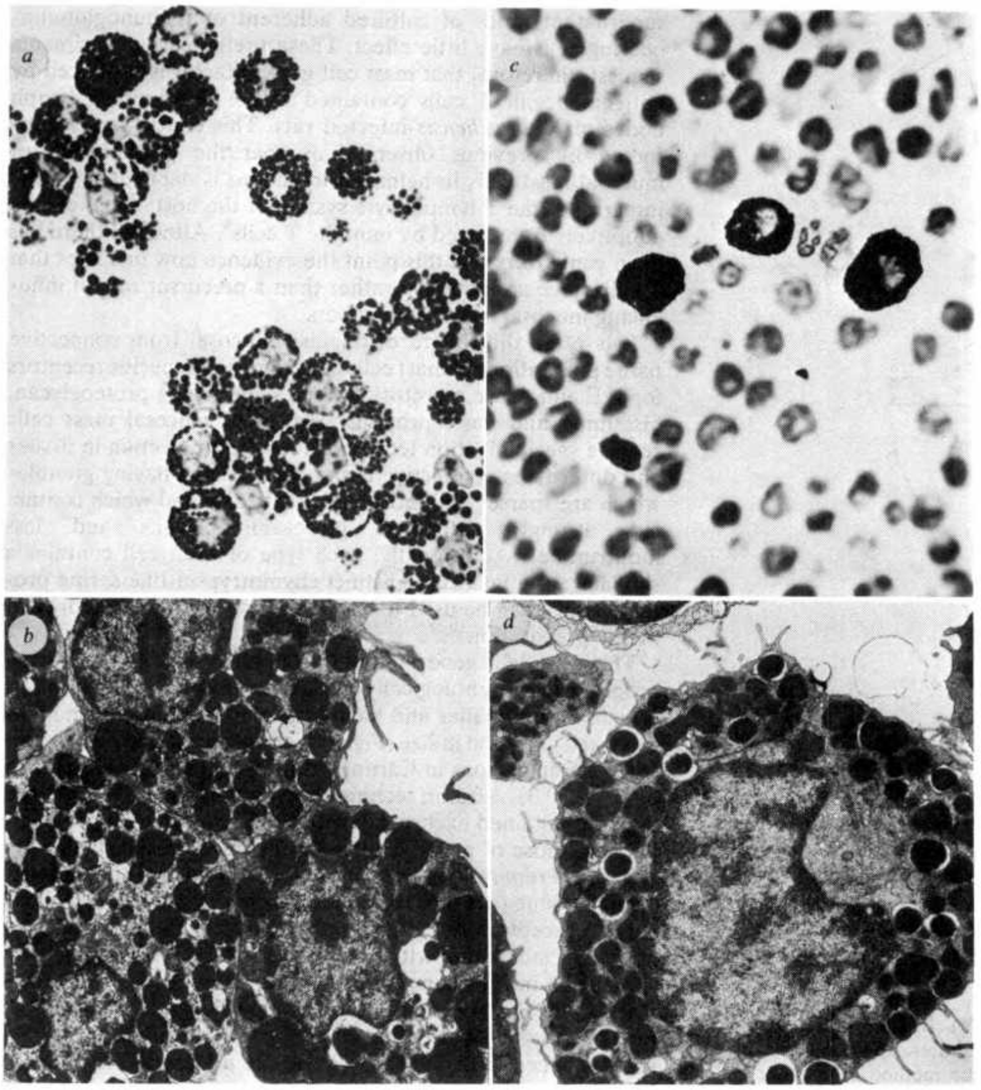

Fig. 2 Morphology of cultured mast cells. For mast cell analysis, bone marrow cells were grown in bulk cultures in 25 cm^2 tissue culture flasks. Bone marrow was allowed to grow for 2–3 weeks with weekly refeeding and restimulation with 10% fresh conditioned medium. During this time mast cells proliferated to form greater than 90% of the total cell population. Cells in suspension cultured for 21 days were fixed in Karnovsky's aldehyde fixative[26] and were pelleted and post-fixed in osmium followed by routine dehydration and Epon embedding. *a*, 1 μm section (× 745) stained with methylene blue/azure II. *b*, EM preparation (×3,800) stained in section with uranyl acetate and lead citrate. For comparison, peritoneal exudate cells from syngeneic rats treated in exactly the same way are shown: *c*, 1 μm section (×745) of peritoneal exudate cells. *d*, EM preparation (×5,300) of peritoneal mast cell.

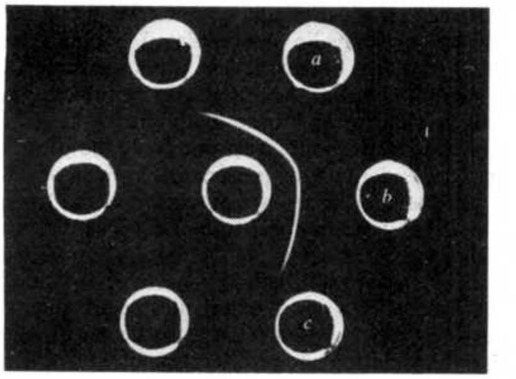

Fig. 3 Double immunodiffusion in 1% agarose to determine the presence of mucosal mast cell protease in extracts of cultured mast cells. Mucosal mast cell protease was purified from small intestine as previously described[27]. Specific antiserum against mucosal mast cell protease was prepared by injecting rabbits with 50 μg of protease with complete Freund's adjuvant at weekly intervals. Each well contained 30 μl of sample. Centre well, anti-mucosal mast cell protease; *a*, purified protease (150 μg ml^{-1}); *b*, 0.15 M KCl extract (200 μl) of pelleted cells from a culture containing 2×10^6 mast cells; *c*, 0.15 M KCl extract of syngeneic rat peritoneal cells containing 1.9×10^6 mast cells. The results show that the extract of the cultured cells contains a high level of mucosal mast cell protease indicating the presence of mucosal mast cells in the culture. The quantity of mucosal mast cell protease in the cell extract, measured by radial immunodiffusion, was 26 μg per 10^6 mast cells, representing approximately 13% of the soluble mast cell protein.

The role of position in determining homoeotic gene function in *Drosophila*

Gines Morata & Stephen Kerridge

Centro de Biología Molecular, CSIC, Facultad de Ciencias,
Universidad Autónoma de Madrid, Canto Blanco, Madris-34, Spain

Homoeotic mutations of *Drosophila* lead to the replacement of one structure by another, for example, *Antennapedia*[1] replaces the antenna with a mesothoracic leg and *bithorax* produces an anterior wing instead of the anterior haltere. The transformed structures differentiated by the homoeotic mutants are essentially normal—only the position in which they appear is abnormal. The mutant phenotypes suggest that in normal development homoeotic genes are involved in developmental alternatives and contribute to a genetic address that defines the particular developmental pathway taken by a primordial group of cells[2–5]. Thus, in the absence of homoeotic gene function, primordia in different positions should follow the same basic developmental pathway. This is indeed the case for embryos that show no activity of *bithorax* genes; thoracic and abdominal segments develop as mesothorax[6]. The simplest view on homoeotic gene function is that the genes act selectively on primordia depending on their position in the embryo. To test this hypothesis, we used a mutation at the *Antennapedia* locus, *Antp*^{73b}, which transforms the antenna into a mesothoracic leg, and we observed the function of the homoeotic genes *engrailed* and *Ultrabithorax* in two apparently morphologically identical appendages which develop from primordia in different positions. Our results indicate that position is the relevant factor in the function of these two homoeotic genes.

We have considered the antennal primordium which normally gives rise to the eye, head and antenna of the fly, and the ventral mesothoracic primordium which produces the second leg. Two differences have been described for these two primordia with regard to the function of *engrailed* and *Ultrabithorax*: (1) the subdivision of the original primordium into anterior and posterior polyclones occurs at about 72 h of development (mid-larval period[7,8]) in the antennal cells, whereas it occurs at about 3 h (blastoderm period) in the mesothoracic leg[9]. As the function of the *engrailed* gene is required for maintenance of the antero-posterior boundary[10–12], this indicates that *engrailed* is active in the mesothorax much earlier than in the antennal segment. (2) Mutations at the *Ultrabithorax* locus (*Ubx*) produce an homoeotic transformation of the posterior mesothoracic leg compartment into the homologous prothoracic one[13,14]. These mutations have no effect on antennal development, which indicates that the *Ultrabithorax* gene is active in the leg but not in the antenna.

There are two sets of legs of mesothoracic type in flies heterozygous for the dominant mutation *Antp*^{73b}: one in the normal position of the second leg (henceforth referred to as the thoracic leg) and the other in the position of the antenna (to be referred to as the cephalic leg). The bristle pattern of the cephalic leg is typically mesothoracic (Fig. 1). We have studied the period of function of *engrailed* by timing the establishment of the antero-posterior boundary in the cephalic and thoracic legs and the respective requirements for *Ultrabithorax* activity.

In these experiments we induced clones that were marked genetically (for details see Table 1 legend) in different developmental stages to determine the time at which the anterior (A) and posterior (P) compartments of the leg are established. Before this time, individual clones can extend to both compartments but thereafter they cannot (see Table 1). In the thoracic leg, A and P polyclones are segregated after 4±2 h (blastoderm period) which agrees with the results obtained in non-*Antennapedia* flies[9]. By contrast, clones in the cephalic leg can extend to both compartments until the mid-larval period (84 ±12h after oviposition, *Minute* time). This is about the time when the antero-posterior subdivision occurs in the normal antenna[8].

We compared the effects of the lack of *Ubx* activity in the cephalic and thoracic legs of *Antennapedia* flies. It has been found recently[13,14] that the loss of *Ubx*$^+$ function in early embryogenesis (blastoderm stage) means that the posterior compartments of mesothoracic and metathoracic legs develop as the posterior compartment of the prothoracic one. The loss of *Ubx*$^+$ function at later times does not affect the mesothoracic leg; the metathoracic leg, however, is then transformed into a mesothoracic one. Thus, there is an early function of the *Ubx* gene necessary for the normal development of meso- and metathoracic legs and also a later function necessary for metathoracic development.

We have generated, by X-ray-induced mitotic recombination, *Ubx*$^-$ clones in *Antennapedia* flies. Genetic mosaics must be used as *Ubx* mutants are zygotic lethal. Most of the *Ubx*$^-$ clones were induced at the blastoderm stage although some were also induced during the larval period as it was conceivable that the cephalic leg might show a temporal succession of mutant phenotypes as in the case of the metathoracic leg[13]. Appropriate genetic combinations were constructed (details are given in

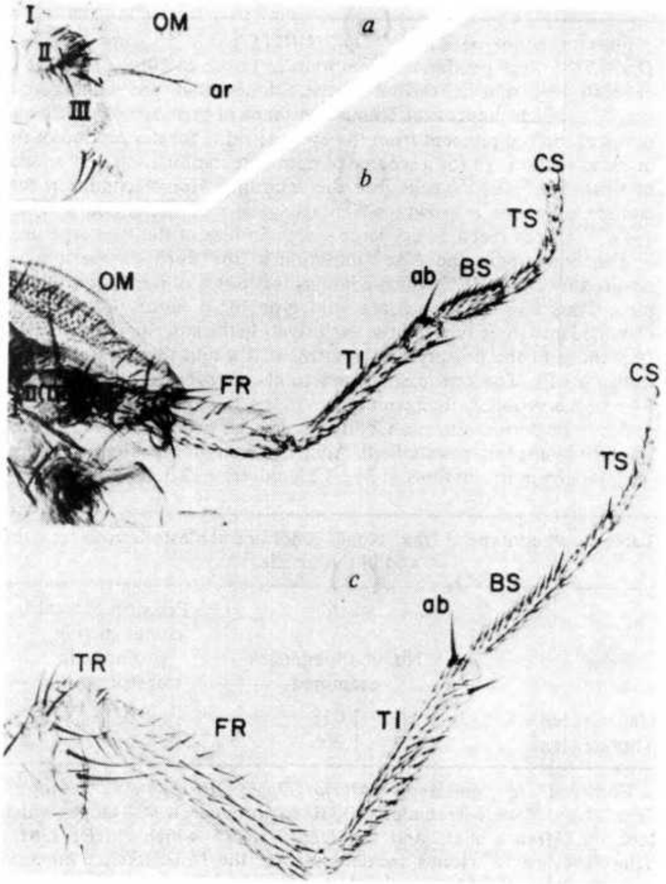

Fig. 1 The cephalic (*b*) and the second (*c*) legs of *Antp*^{73b} flies showing the close similarity between them. A normal antenna (*a*) is included for comparison. The three appendages are shown at the same magnification. The three antennal segments (I, II and III) and arista (ar) are indicated. The apical bristle (ab), typical of the mesothoracic pattern is present in both legs whereas landmarks of first and third leg patterns, such as anterior and posterior transverse rows, are absent. In general, the first antennal segment remains untransformed and the second is modified towards the trochanter. The transformation into leg of mesothoracic type is usually complete distal from the trochanter, although sometimes arista structures remain in the tarsal region. TR, trochanter; FR, femur; TI, tibia; BS, basitarsus; TS, tarsal segments; CS, claws; OM, ommatidia.

0028-0836/82/450191—02$01.00

Table 2 legend) to allow the detection of *Ubx*$^-$ clones. We found that in the thoracic (second) leg, most *Ubx*$^-$ clones induced at blastoderm showed the prothoracic transformation in the posterior compartment (Table 2). However, clones of the same genotype and initiated at the same time, failed to show prothoracic transformation in the cephalic leg and instead formed a mesothoracic pattern. In both legs, clones produced during the larval period remained mesothoracic. Thus we conclude that the thoracic leg requires *Ubx*$^+$ activity in early development but the cephalic one does not.

The results presented here demonstrate the importance of position in the function of homoeotic genes. In *Antennapedia* flies the antennal primordium, although it develops into a mesothoracic leg, retains the pattern of homoeotic gene function (at least for *en* and *Ubx*) characteristic of the normal antenna. The thoracic legs in *Antennapedia* flies develop normally with respect to *en* and *Ubx*. The critical factor for the activity of these genes seems to be the position occupied by the primordial cells, not the identity of the structure into which they develop. This conclusion, however, is based on the assumption that there is no difference other than position between the cephalic and thoracic primordia of *Antennapedia* flies. This assumption—although very reasonable, as both primordia develop into the same structure—cannot be rigorously proven at present.

Table 1 Establishment of the antero-posterior segregation in cephalic and thoracic legs

Age at clone initiation	No. of clones found in anterior and posterior compartments: Cephalic leg *n*	A	P	A+P	Thoracic leg *n*	A	P	A+P
Blastoderm (4±2 h)	1,202	12	9	15	1,330	26	10	0
36±12 h 60±12 h	832	17	14	10	—	—	—	—
84±12 h	394	17	9	1	—	—	—	—

Flies of genotype *M(1)o*^{Sp}*Dp(3;1)P115/y w f*^{36a}; *Antp*^{73b} *Ubx*^{1}/*Dp(3; 3)P5* were irradiated as embryos or larvae at 500 or 1,000 R to generate, by mitotic recombination, clones that are homozygous *y w f*^{36a} (which changes the colour and shape of bristles and cuticle and removes the red pigment from the eye; see ref. 1 for description of the markers and ref. 13 for a scheme of mitotic recombination very similar to this). The *y w f*^{36a} cells lose the retarding *Minute* condition that confers on them a growth advantage over their neighbours. Thus, *y w f*^{36a} clones reach a very large size[15]. In flies of the genotype used in this experiment the *Ubx*^{1} mutation in the third chromosome is covered by *Dp(3; 3)P5* which contains two doses of the *bithorax* complex. Thus *y w f*^{36a} clones are wild type for *bithorax*. Clones were classified into three types: those exclusively in the anterior compartment (A), those in the posterior compartment (P), and those extending to both (A+P). The one case of apparent anteroposterior crossing at 84±12 h is probably the result of two independent clones, one anterior and one posterior (the probability of such an event was 0.45 for the number of appendages studied). Age is given in hours after egg laying. The data from irradiations at 36±12 h and 60±12 h are pooled.

Table 2 Phenotype of *Ubx*$^-$ clones generated at blastoderm in cephalic and in thoracic legs

	No. of appendages examined	Fraction of total clones showing prothoracic transformation
Cephalic leg	1,018	0/18
Thoracic leg	1,008	6/9

Embryos of genotype *M(1)o*^{Sp}*Dp(3; 1)P115/y w f*^{36a}; *Antp*^{73b} *Ubx*^{1}/*Ubx*^{130} were irradiated (500 R) to produce *y w f*^{36a} clones which lack the *Minute* allele and the *Dp(3; 1)P115* which carries *Ubx*$^+$. Therefore, *y w f*^{36} clones are defective for the *Ultrabithorax* function and because of the *Minute* effect[15] reach a very large size which permits an unequivocal identification of the bristle pattern as prothoracic or mesothoracic. Clones producing prothoracic transformation are represented as a fraction of the total number of clones found in the posterior cephalic and second thoracic legs. We also found *y w f*^{36a} clones in the third posterior thoracic leg (metathoracic) which showed (8/10) prothoracic transformation. The reason why not all clones in the thoracic legs showed prothoracic transformation is purely technical. In the recombination system used there are always several *y w f*^{36a} clones which arise after mitotic recombination distal to *Dp(3; 3)P115* and hence retain the *Ubx*$^+$ gene. These have been estimated to represent 20% of the total *y w f*^{36a} clones[13,14]. Clones generated after the blastoderm period do not show prothoracic transformation in either the cephalic (0/34) or thoracic (0/10) legs, in agreement with previous results[13,14].

The lack of activity of *Ubx* in the cephalic leg poses an intriguing question about the development of the legs; if the normal development of a leg of mesothoracic type requires (at least in the posterior compartment) a decision prothorax–mesothorax[13] which is implemented genetically through one of the functions—postprothorax—controlled by the *Ultrabithorax* gene, then one would expect any leg of mesothoracic type to undergo the same decision. But in the case of the cephalic leg of *Antennapedia* that gene function is apparently not required, suggesting that either cephalic and thoracic leg primordia in *Antennapedia* produce the same structure via different sets of decisions or the postprothorax function is provided in the head by another developmentally homologous gene that is inactive in the thorax.

We thank Jim Kennison for a key conversation and Peter Lawrence, Dan Lindsley, Pedro Ripoll and Lenny Robbins for discussions. S.K. is supported by EMBO. Financial help from Comision Asesora del Descuento Complementario is acknowledged.

Epidermal growth factor rapidly stimulates prolactin gene transcription

Epidermal growth factor (EGF) was originally characterized as a growth factor for various cell types[1,2] and was subsequently shown to affect a number of cellular and molecular processes[3,4], of which many might be considered as a part of the pleiotropic growth response (enhanced uptake of glucose, uridine and amino acids and stimulated synthesis of protein, RNA and DNA). Very early responses to EGF, such as increased sodium fluxes[5] and stimulation of tyrosine phosphorylation[6], have been proposed to mediate some or all of EGF's effects. In a number of tissues, EGF has been shown to increase the synthesis of specific proteins[7–10]. We have investigated the effects of EGF on prolactin synthesis in the GH_4 rat pituitary cell line to gain further insight into the mechanism of EGF's actions on cellular

0028–0836/82/450192—03$01.00

functions. Addition of EGF to GH_4 cells results in a three- to sixfold stimulation of prolactin synthesis, as well as a partial inhibition of cell growth[7,8]. In this report, we demonstrate that the increased prolactin synthesis appears to be the result of a rapid stimulation of prolactin gene transcription by EGF. It is tempting to speculate that very early transcriptional effects on specific genes, such as reported here in the case of the prolactin gene in GH_4 cells, may mediate some or all of the later effects of EGF on cell cycle regulation in those cells for which it serves as a growth factor.

The synthesis of prolactin in GH_4 cells is regulated by a wide variety of peptide and steroid hormones[11-13]. Thyrotropin releasing hormone (TRH) stimulates prolactin synthesis in GH_4 cells by acting at the nuclear level to increase the production of prolactin mRNA[14]. The increased steady state content of the primary transcript of the prolactin gene suggested that a transcriptional mechanism was involved. In order to determine whether EGF was also acting at a transcriptional level to increase prolactin mRNA, total cellular poly(A) RNA from control and EGF treated cells was analysed using RNA blotting procedures after size fractionation on denaturing agarose gels[15].

Figure 1*a* shows that EGF promotes an increase in the steady state level of several nuclear prolactin RNA species including the primary transcript. Visualization of the nuclear species is enhanced by hybridizing the blotted RNA with both labelled cloned prolactin gene-specific intervening sequence and prolactin cDNA. Figure 1*b* shows a densitometric scan of the larger prolactin nuclear transcripts. In this experiment, there is approximately a fourfold stimulation of the steady state level of each of the prolactin putative nuclear precursors, including the primary transcript. This is comparable to the three- to sixfold EGF stimulation of mature prolactin mRNA levels which are typically observed.

Because of their presumed very short half life, the steady-state level of prolactin nuclear transcripts has been proposed to accurately reflect prolactin gene transcription[14]. To verify this, the time course of EGF stimulation of prolactin gene transcription was measured by elongating nascent prolactin RNA transcripts in isolated nuclei as well as by quantitating nuclear precursors by Northern gel analysis. The time course of EGF stimulation of prolactin gene transcription, as well as the resultant cytoplasmic prolactin mRNA accumulation is shown in Fig. 2. The close agreement between the two measurements of transcription confirms previous predictions that changes in nuclear RNA precursor levels can represent an accurate estimation of the transcriptional activity of specific genes.

EGF maximally stimulates prolactin gene transcription 10-fold within 1 h, from 2 to 18 p.p.m. per kilobase, using a 0.9 kilobase prolactin genomic intervening sequence probe. This stimulation is followed by a rapid attenuation, such that 3 h following EGF addition prolactin gene transcription is only half of its maximally induced level. The net effect of this burst of prolactin transcription is to rapidly elevate the cytoplasmic prolactin mRNA content. There is a further slower transcriptional attenuation occurring over a period of days and during this time the prolactin mRNA levels remain fairly constant, paralleling the slow decline in transcription. In some cases the attenuation event has been more pronounced such that transcription returns to control levels within the first 36 h, while in others it remains moderately elevated for days. Neither the initial rapid nor subsequent slower attenuation can be accounted for by reciprocal changes in total polymerase II transcriptional activity.

The data summarized in Fig. 2 demonstrate that the kinetics of prolactin mRNA accumulation in response to EGF reflect the kinetics of effects on prolactin gene transcription. Since a steady-state transcriptional effect is not achieved, the kinetics of EGF-stimulated prolactin mRNA accumulation is not a reflection of its cytoplasmic half life. Thus, the accumulation of prolactin mRNA ceases 10 h after the addition of EGF because the increased rate of production of newly transcribed prolactin mRNA sequences no longer exceeds the rate of cytoplasmic decay. When prolactin mRNA stability is estimated under conditions of steady-state transcription, the half-life is approximately 6 h (ref. 16). Following prolonged incubations with EGF, there is an increase in cytoplasmic prolactin mRNA without a concomitant increase in transcription (Fig. 2). The mechanism of this late effect of EGF is the subject of current investigation.

The mechanism of the EGF induced transcription is unclear. There are a variety of second messenger systems which have been associated with EGF. A large body of evidence suggests that the EGF receptor is a tyrosine kinase which is capable of autophosphorylation in addition to the phosphorylation of other membrane proteins[6,17,18]. Various cytoplasmic and cytoskeletal proteins may also be substrates, either directly or indirectly[19]. However, as yet, no nuclear protein has been shown to be modified by tyrosine phosphorylation in response to EGF treatment. EGF stimulation of sodium fluxes has also been suggested as a critical intermediate in the regulation of cellular processes by EGF[5]. Increased cytoplasmic sodium can affect the homeostasis of other ions including calcium[20], which has been suggested to play a role in regulating prolactin gene expression[21].

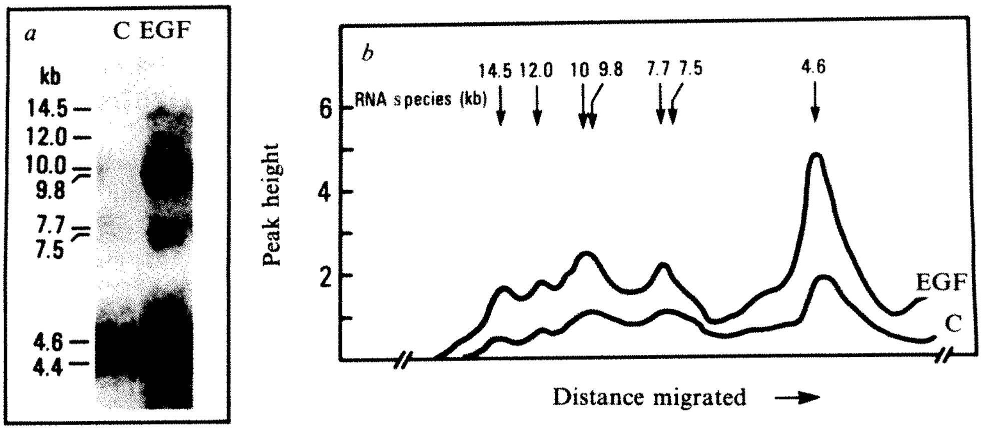

Fig. 1 Effects of EGF on the level of nuclear prolactin RNAs. *a*, Poly(A) RNA was prepared from control GH_4 cells (C) and from cells treated with 5×10^{8} M EGF for 24 h (EGF) as previously described[14]. Aliquots of 12 μg of each RNA were denatured by heating (65 °C) in sample buffer (10 mM NaH_2PO_4, *p*H 7.4, 2.2 M formaldehyde, 50% (v/v) formamide). After electrophoresis on a 1.5% agarose gel containing 1.1 M formaldehyde, the RNA was transferred to 'diazotysed' paper (DBM). The RNA was hybridized with 10^7 c.p.m. per ml of both nick-translated prolactin cDNA and prolactin gene specific intervening sequence, pIVSc (specific activity 3–8×10^{8} c.p.m. per μg with [α-^{32}P]dCTP) for 16 h at 42 °C. The autoradiogram was exposed for 2 days to clearly visualize the larger nuclear prolactin RNAs. The lower portion of the gel containing mature prolactin mRNA was drastically overexposed and is not shown. The sizes of the prolactin nuclear RNAs are extrapolated from the migration of 18S and 28S RNA. The largest (14.5 kb) species (alternatively determined to be 12.5 kb when DNA standards are used, data not shown) appears to be the true size of the gene (S. Supowit *et al.*, in preparation) and is therefore referred to as the primary transcript. *b*, Densitometric scan of the autoradiograph shown in *a*. Stimulation of each nuclear prolactin RNA (based upon comparison of peak areas) is approximately 3.8-fold.

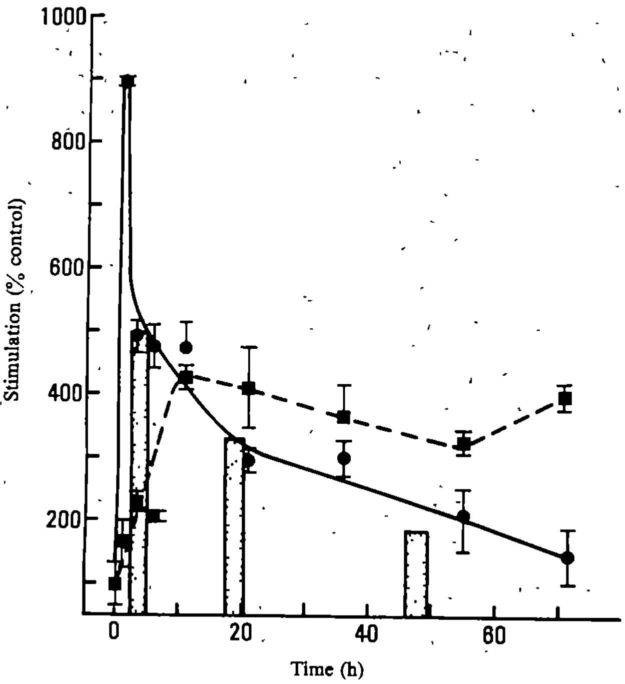

Fig. 2 Time course of EGF stimulation of prolactin gene transcription rate (●), prolactin precursor RNA level (stippled bars) and cytoplasmic prolactin mRNA (■). GH_4 cells were incubated with 5×10^{-8} M EGF for the indicated times before being collected by scraping into iced phosphate-buffered saline (PBS). After washing in PBS, cells were lysed by gentle homogenization in 150 mM KCl, 5 mM $MgCl_2$, 5 mM DTT, 10 mM Tris *p*H 7.8, 0.1% Nonidet P-40. After low-speed centrifugation, total RNA was prepared from the cytoplasm by phenol/chloroform extraction. Aliquots of 20 μg were bound to 1 cm squares of activated DBM paper and hybridized to excess nick-translated cloned prolactin cDNA to quantify prolactin mRNA content. Each point represents the mean ± s.e. of triplicate determinations. The nuclear pellets were washed in the nascent chain labelling buffer (150 mM KCl, 5 mM $MgCl_2$, 1 mM $MnCl_2$, 10 mM Tris, *p*H 7 8, 10% glycerol). Nuclei were then incubated (25 °C, 45 min) in the same buffer supplemented with 1 mM ATP, CTP and GTP and 200 μCi [^{32}P]UTP (200–400 Ci mM^{-1}) allowing nascent transcripts to elongate. Labelled RNA was purified and quantified as described in refs 24 and 25. Briefly, $8–15\times10^6$ c.p.m. of ^{32}P-labelled RNA was hybridized to 2 μg of a 0.9 kb subcloned fragment of a prolactin gene specific intervening sequence (pIVSc) bound to a 3 mm disk of nitrocellulose Each point is the mean ± s.e. of the transcription rate (specific c.p.m. bound/c.p.m. added) based upon triplicate hybridizations. Both control and EGF stimulated prolactin gene transcription is undetectable when α-amanitin (0.8 μg ml^{-1}) is included in the incubation. The hybridization is linear with added labelled RNA and constant with variable DNA/filter (0.5–5.0 μg). The use of a cloned intervening sequence fragment during the hybridization prevents variable competition by accumulated mRNA. Total cellular poly(A) containing RNA was prepared from cells treated in parallel. Prolactin RNA precursors were quantified as described in Fig. 1. For comparison purposes all data are expressed as percent control. Basal-prolactin gene transcription rate in GH_4 cells is 2 p.p.m.; maximal stimulation is 18 p.p.m. Basal prolactin mRNA level is 1,200 molecules per cell; maximal stimulation is 5,300 molecules per cell

Alternatively, it is possible that a direct interaction of rapidly internalized EGF–receptor complexes with the nucleus mediates the transcriptional effects. However, the shape of the time course of prolactin transcriptional stimulation, a burst followed by rapid attenuation, is consistent with the time course of the binding of EGF to surface receptors in cultured cells, a transient maximum followed by rapid internalization[22]. This time course is distinct from the gradual constant accumulation of nuclear membrane bound EGF[23]. These data suggest that the putative nuclear binding events are not involved with the transcriptional regulation of prolactin.

An increase in prolactin gene transcription rate appears to be the major, if not sole, mechanism for the EGF stimulation of prolactin synthesis in GH_4 cells. The burst-attenuation kinetics of the transcriptional stimulation result in the rapid elevation of the cytoplasmic prolactin mRNA to the maximal levels. This result demonstrates that caution should be exercised in interpreting half times of accumulation as a reflection of message stability. We suggest that burst-attenuation transcriptional kinetics could be an important physiological mechanism for rapidly increasing the cytoplasmic content of specific long-lived mRNAs to new steady-state levels in response to external stimuli. The stimulation of prolactin transcription by EGF is too rapid to be a secondary consequence of any effect on the cell cycle and kinetic analysis suggests that the transcriptional effects are closely linked to the interaction of EGF with its receptor on the surface of the cell. It is likely, therefore, that regulation of prolactin gene transcription is mediated by a process that is common to the actions of EGF in other target tissues including those for which it is a positive growth factor. Transcriptional regulation of a specific protein(s) is, therefore, proposed to be among the 'early' events produced by growth factors, and may mediate the observed regulation of the cell cycle by growth factors.

We thank Estelita S. Ong for her assistance, Dr Scott Supowit for preparing the intervening sequence clone, and Margaret Richards for typing of the manuscript. Kinetics of sickle haemoglobin polymerization in single red cells

Massimo Coletta*, James Hofrichter, Frank A. Ferrone* & William A. Eaton

Laboratory of Chemical Physics, National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases, Building 2, Room B1-04, National Institutes of Health, Bethesda, Maryland 20205, USA

Kinetic studies on solutions of purified haemoglobin S indicate that the rate of intracellular polymerization is an important variable in the pathophysiology of sickle cell disease[1–4]. Until now, however, no experimental technique has been available to measure directly the kinetics of intracellular polymerization. Indirect methods, which use visual determination of cellular shape changes or changes in filterability of red cell suspensions, have given apparently conflicting results[5–9]. Here we report our initial results on the application of a laser-photolysis, light scattering technique to measure directly the kinetics of haemo-

globin S polymerization in single red cells. In our experiment, deoxyhaemoglobin S is rapidly formed by photolysing the carbon monoxide complex with an argon ion laser focused inside the cell, and the change in scattered light is used to detect the appearance of polymer. We find a very wide distribution of delay times, ranging from 1 ms to >100 s, indicating that the polymerization inside red cells proceeds by the same nucleation and growth mechanism as in solutions of purified haemoglobin S[10].

Red cells from patients with homozygous sickle cell disease were washed and diluted to a volume fraction of about 0.001 in a buffer consisting of 0.12 M sodium chloride, 2.4 mM potassium chloride, 15 mM disodium hydrogen phosphate, 2.5 mM sodium dihydrogen phosphate, 5.5 mM dextrose and $1\ \mathrm{g\ l^{-1}}$ bovine serum albumin. The oxygen in the cell suspension was exchanged for carbon monoxide, and sodium dithionite was then added anaerobically to a final concentration of 10 mM to remove any remaining traces of oxygen. The final room temperature *p*H was 7.4, and the osmolality determined from the freezing point depression was 290–300 mOsmol. Cells were sedimented onto the top coverslip of a thermostated Dvorak–Stottler flow cell[11]. An argon ion laser at 514 nm was focused inside a single red cell to a diameter of 3 μm (full width at half peak intensity) with a thermostated 90× oil immersion objective having a numerical aperture of 1.32. The laser was directed to the objective via a half-silvered mirror mounted above it at 45°. Light reflected and scattered by the red cell was collected by the objective, focused with an eyepiece onto a pinhole with a diameter of the magnified image of the cell, and projected onto a photomultiplier tube with a second eyepiece, using a Leitz MPS photometer attachment. The directly reflected laser beam was blocked by masking the centre of the tube lens mounted above the half-silvered mirror. Laser heating of the red cell was determined in experiments on cresol red to be less than 1 °C at the centre of the beam using a peak power density of $\sim 1{,}000\ \mathrm{W\ cm^{-2}}$ to achieve full photolysis.

To investigate the kinetics of intracellular polymerization at 37 °C systematically, progress curves were recorded for 453 different cells from four patients with homozygous sickle cell (SS) disease. Cells were never kept at 37 °C for more than 3 h, as previous experiments had indicated that changes in the kinetics occurred after this time. Cells were chosen at random and no results were excluded from the data analysis.

Figure 1 shows representative progress curves for sickle cells, for normal cells and for solutions of purified haemoglobin S. Normal cells gave a noisy signal which did not change with time. A variety of progress curves were observed for sickle cells. These could be roughly divided into two types. The first type resulted from the most rapid intracellular polymerization, and was very similar to that found for polymerization from solution. There was a clear delay followed by a sudden increase in light scattering, where the average increase in the scattered intensity was the same as that found for solution polymerization. A significant difference between the solution and cell progress curves was that the increase in light scattering was accompanied by a marked decrease in the amplitude of the noise (Fig. 1). The amplitude of the noise during the delay period was much greater than that found for solution, and was very similar to the noise observed for normal cells (Fig. 1). The noise from normal cells and from sickle cells during the delay period probably corresponds to the previously described 'flicker phenomenon', which is thought to arise from brownian motion[11–14]. Fluctuations in cell thickness from brownian motion could produce fluctuations in the measured intensity by modulating the interference between laser light reflected from the top and bottom cell surfaces. The increase in internal viscosity resulting from polymer formation would then decrease the noise by damping the thickness fluctuations.

The second type of progress curve was found for cells exhibiting apparently slow intracellular polymerization. These curves showed a sudden and pronounced decrease in the amplitude of the noise, but the change in average light scattering following the noise decrease varied enormously from cell to cell, and in repeated measurements on the same cell. We interpret these distorted kinetic progress curves as resulting from cell motion that is occurring simultaneously with polymer formation, that is, morphological 'sickling'[5–9]. For these cells the delay time was taken as the time of the decrease in noise. Visual observations showed that there was no morphological change in the cell during the delay period measured in this way.

For delay times less than 0.03 s almost all cells exhibited polymerization type progress curves, while for cells with delay times longer than about 3 s there was no increase in light scattering from polymerization following the delay period. Of the 453 cells examined, 276 (61%) exhibited solution type polymerization progress curves, 146 (32%) exhibited progress

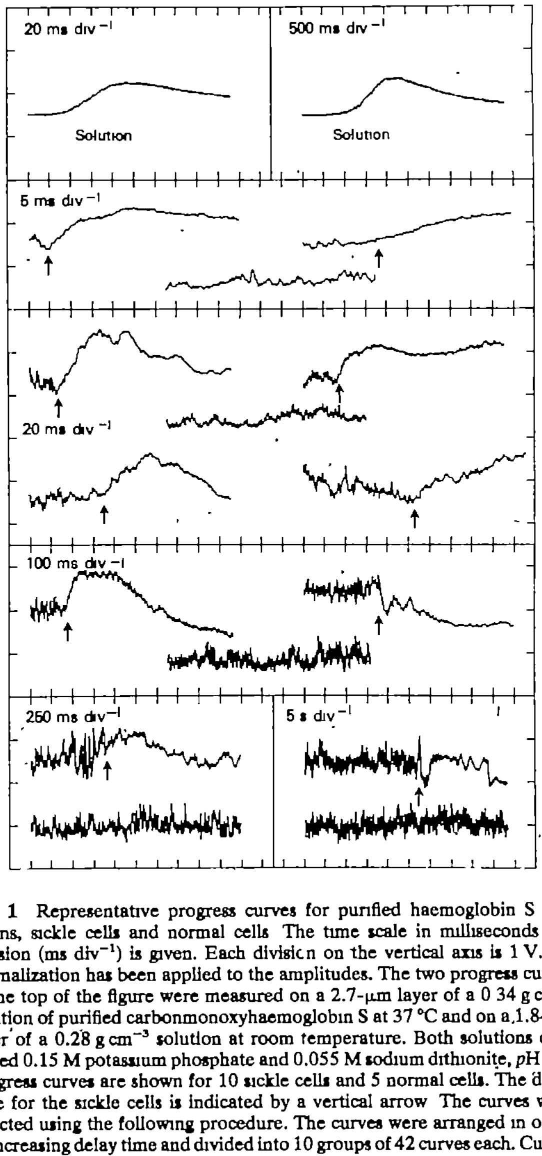

Fig. 1 Representative progress curves for purified haemoglobin S solutions, sickle cells and normal cells. The time scale in milliseconds per division (ms $\mathrm{div^{-1}}$) is given. Each division on the vertical axis is 1 V. No normalization has been applied to the amplitudes. The two progress curves at the top of the figure were measured on a 2.7-μm layer of a $0.34\ \mathrm{g\ cm^{-3}}$ solution of purified carbonmonoxyhaemoglobin S at 37 °C and on a 1.8-μm layer of a $0.28\ \mathrm{g\ cm^{-3}}$ solution at room temperature. Both solutions contained 0.15 M potassium phosphate and 0.055 M sodium dithionite, *p*H 7.1. Progress curves are shown for 10 sickle cells and 5 normal cells. The delay time for the sickle cells is indicated by a vertical arrow. The curves were selected using the following procedure. The curves were arranged in order of increasing delay time and divided into 10 groups of 42 curves each. Curves were chosen as 'representative' if they met the following criteria: (1) the delay time was within half the standard deviation from the average delay time for the group (except for the group containing cells with the longest delay times), (2) the polymerization amplitude (1.0±0.5 V) and the offset (1.8±0.9 V) were within half the standard deviation for the mean of all measurements; (3) the peak-to-peak noise before and after the delay were within 1 s.d from the mean for the group. 32 out of the 422 curves met these criteria

* Present addresses: Facolta di Medicine e Chirurgia, II Cattedra di Chimica e CNR Centro di Biologia Molecolare, Universita di Roma, Citta Universitaria, 00185 Roma, Italy (M.C.), Department of Physics and Atmospheric Science, Drexel University, Philadelphia, Pennsylvania 19104, USA (F.A.F.)

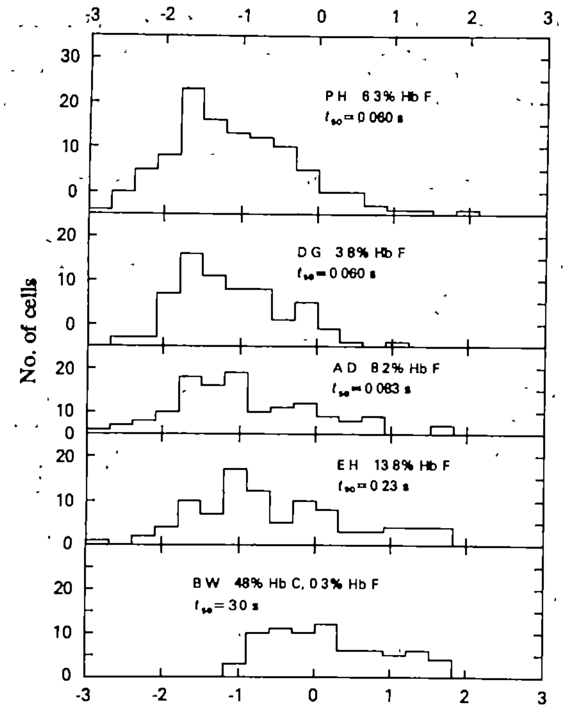

Fig. 2 Histogram of delay times on a logarithmic scale at 37 °C for red cells from four patients with homozygous SS disease and one patient with SC disease The median delay time (t_{50}) and per cent fetal haemoglobin (Hb F) measured by the alkaline denaturation method are given in the figure. The number of cells with delay times >50–100 s were 4 out of a total of 155 cells for patient P.H., 4 of 105 for D.G., 4 of 87 for A.D., 6 of 101 for E.H., and 21 of 94 for B.W. These cells were included in the calculation of the median delay time.

curves with delay times determined by the noise decrease, 13 (3%) exhibited uninterpretable progress curves and 18 (4%) exhibited progress curves similar to normal cells for 50–100 s, with no morphological evidence of intracellular polymerization at the end of this observation period. Progress curves were not recorded for more than 50–100 s, as this would have significantly slowed data collection.

An interesting difference between cells exhibiting rapid and slow polymerization was found in the reproducibility of the delay time. In a separate series of experiments progress curves were measured repeatedly on 13 cells with mean delay times ranging over 0.05 to 11 s. For the nine cells with mean delay times <3 s the percentage standard deviation from the mean was 19%, with a range of 10–36%. Measurements could be repeated an average of 23 times (range 11–30) before the morphological change produced by intracellular polymerization became irreversible, and further experiments yielded uninterpretable progress curves. For the four cells with mean delay times longer than 3 s, the measurements could be repeated on average only 11 times (range 8–14), and the delay times were much less reproducible, with an average standard deviation of 71% (range 52–99%). This irreproducibility of long delay times is also characteristic of polymerization in solution, and has been previously interpreted as arising from the stochastics of the homogeneous nucleation of single polymers in the small sample volumes (5×10^{-11} cm^3)[10].

Figure 2 gives the main results of our kinetic study, which shows the delay time histogram for the four patients with homozygous SS disease. There is an extremely wide distribution of delay times, varying from 1 ms to >100 s. This wide range of delay times was expected[1] from the known heterogeneity in intracellular haemoglobin S concentration[15] and the enormous sensitivity of the delay time of solution polymerization to initial haemoglobin S concentration (delay time is inversely proportional to the 15th to 40th power of concentration)[1,10,16]. Solution studies have shown that other variable cellular factors, such as pH[16,17] and 2,3-diphosphoglycerate levels[18,19], are relatively unimportant in determining the delay time.

To compare quantitatively the delay times observed in cells and in isolated solutions, we calculated the distribution of intracellular haemoglobin S concentrations from the delay time histogram (Fig. 3). For this calculation we used the sum of the delay time histograms for the three patients with fetal haemoglobin levels below 9% and the concentration dependence of the delay time measured on purified haemoglobin S solutions using a similar laser-photolysis light scattering technique[10]. The calculated distribution in Fig. 3 yields a mean value of 0.32 g cm^{-3} for the intracellular haemoglobin S concentration, which is in excellent agreement with the mean value of 0.30 ± 0.02 to 0.32 ± 0.02 g cm^{-3} measured by conventional methods[15,20–22]. The concentration distribution shows that the intracellular haemoglobin S concentration extends to >0.40 g cm^{-3}, in agreement with measurements on density fractionated cells[15,23] (M. R. Clark and S. B. Shohet, personal communication). The extension of the calculated distribution to very low values of haemoglobin S concentration presumably results from the cells containing a large fraction of haemoglobin

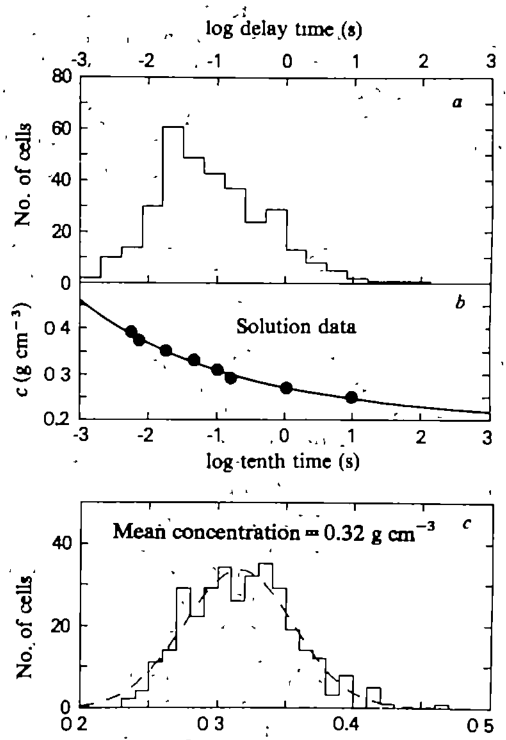

Fig. 3 Determination of the concentration distribution in sickle cells from the delay time distribution. *a*, This histogram of delay times on a logarithmic scale is the sum of the histograms from Fig. 2 for patients P.H., D.G. and A.D. The histogram from patient E.H. was not included, as the fetal haemoglobin content of 13.8% is more than 2 s.d. from the mean of 5.6 ± 3.6% found for sickle cell patients[20,21]. *b*, The concentration of purified carbonmonoxyhaemoglobin S is plotted against the logarithm of the tenth-time. The tenth-time is the time required to reach 1/10 of the polymerization amplitude, and is not significantly different from the delay time taken as the time of onset of a measurable increase in light scattering, which was the criterion used for the sickle cell progress curves. The data (filled circles) were obtained by Ferrone *et al.*[10], using the same laser-light scattering photolysis technique for purified haemoglobin S at 35 °C in 0.15 M potassium phosphate buffer, 0.055 M sodium dithionite, pH 7.1. The curve through the data is a least-squares fit of the empirical function c (g cm^{-3}) = $a\exp(-bx+dx^2)+e$, where x is the logarithm of the tenth-time in seconds, $a=0.104$, $b=0.287$, $d=0.021$ and $e=0.167$). In carrying out the fit the data points were weighted according to the reciprocal of their standard errors. *c*, The histogram of intracellular haemoglobin S concentrations was obtained by calculating the concentration corresponding to each delay time with the empirical function used to draw the curve in *b*. The data are reasonably well represented by a gaussian function (dashed curve), $P=a\exp(-(b-c)/d)^2$, where c is the intracellular haemoglobin S concentration in g cm^{-3}, $a=33.5$, $b=0.316$, $d=0.057$. The detailed shape of the concentration distribution is least certain above 0.40 g cm^{-3}, where there are no solution data.

F[24], which is known to increase the delay time markedly[3,25]. The high fetal haemoglobin content in the cells from patient E.H., moreover, is most probably responsible for the shift of the delay time distribution (Fig. 2) to longer times.

The close correspondence of the calculated and measured concentration distributions, the similarity in shape of the cell and solution polymerization progress curves, and the irreproducibility of the long delay times in cells together argue strongly that polymerization of haemoglobin S inside cells proceeds by the same nucleation and growth mechanism as in purified solutions. The results of a previous kinetic study, which showed that red cell membrane components have no significant effect on the delay time of purified solutions[26], considerably strengthen this conclusion.

Delay time measurements on cells should provide a sensitive method for assaying potential therapeutic agents. To evaluate the results, however, it will first be necessary to establish criteria for effectiveness by measuring delay time distributions for sickle cell syndromes of varying clinical severity. As an example, we have measured the distribution of delay times from a patient with sickle cell haemoglobin C (SC) disease (Fig. 2). The median delay time (t_{50}) is 3 s, much longer than the t_{50} of 0.06–0.23 s for the SS patients (Fig. 2). The delay time distribution found for SC cells is consistent with the clinical finding that SC disease is intermediate in severity between SS disease and the essentially benign sickle cell trait[20], in which the delay times are much longer[7,27].

We thank Patricia Griffith and Arthur W. Nienhuis for their cooperation and continuous supply of blood samples that made this study possible, also H. Franklin Bunn for many helpful discussions and for critically reading the manuscript. M.C. was a recipient of a Fogarty International Junior Fellowship.

Protein dynamics and NMR relaxation: comparison of simulations with experiment

Comparisons between molecular dynamics simulations of proteins and experiment have been based on temperature factors[1–5] derived from X-ray spectra and on the stability of hydrogen bonds[6]. Here we present a novel method of testing molecular dynamics simulations against nuclear magnetic resonance (NMR) relaxation measurements, based on the recently developed model-free approach[7] to the interpretation of NMR data. As NMR relaxation in proteins is determined by dynamics on the picosecond–nanosecond time scale, a comparison of NMR experiments and molecular dynamics simulations that last for less than ~100 ps is more meaningful than previous ones[3–6] involving much longer time scales. We make contact between a molecular dynamics simulation[8] and a ^{13}C-NMR relaxation study[9] of pancreatic trypsin inhibitor (PTI) by comparing generalized order parameters (which are measures of the extent of angular motion of the bonds) extracted from the relaxation data[9] with those calculated[10] from a 96-ps trajectory[8]. We show that the theoretical order parameters indicate less motion than their experimental counterparts. The relative flexibility of the residues studied, however, is reasonably well described by the simulation.

At presently available spectrometer frequencies, ^{13}C-NMR relaxation of protonated carbons is determined by the reorientation of the ^{13}C—H bond vectors relative to the external magnetic field. For a protein in solution both the motion of the macromolecule as a whole and internal motions in a macromolecule-fixed frame contribute to the relaxation. It has been shown recently[7] that the unique information on fast internal motions contained in NMR relaxation experiments can be specified by two model-independent quantities: an effective correlation time, τ_e, and a generalized order parameter, $\mathcal{S}$. These quantities can be extracted from relaxation data using a simple fitting procedure[7]. τ_e is proportional to the area of the time correlation function for internal motions; the time correlation function can have components which decay with correlation times faster or slower than τ_e. For ^{13}C-NMR of protonated carbons, $\mathcal{S}$ is a measure of the angular restriction of the motion of a ^{13}C—H vector and is defined as

$$\mathcal{S}^2 = \frac{4\pi}{5} \sum_{m=-2}^{2} |\langle Y_{2m}(\Omega)\rangle|^2 \tag{1}$$

where Y_{2m} are spherical harmonics, Ω specifies the orientation of a ^{13}C—H bond in a macromolecule-fixed frame and the angular brackets denote an average over all possible orientations accessible on a time scale shorter than the correlation time for the overall reorientation of the macromolecule (~4 ns for PTI). It follows from equation (1) that $0 \leq \mathcal{S}^2 \leq 1$ and that $\mathcal{S} = 0$ when the internal motion is isotropic, while $\mathcal{S} = 1$ when the motion is completely restricted.

Values of $\mathcal{S}$ and τ_e of ^{13}C—H bonds for 12 methyl groups have been extracted[7] from the relaxation data of Richarz *et al.*[9]. The τ_e values which contain contributions due to motions of and about the symmetry axis of the methyl groups, were in the range 19–70 ps.

As in the molecular dynamics simulation of Karplus and McCammon[8] the hydrogens are incorporated into the heavy atoms to which they are bound, it is impossible to calculate $\mathcal{S}$ and τ_e for methyl groups directly from their trajectory. However, a comparison with experimental order parameters becomes possible if it is assumed that the motion of the methyl symmetry axis (for example, the C$^\alpha$—C$^\beta$ bond in alanine) and the motion of the protons about this axis are uncoupled. In this

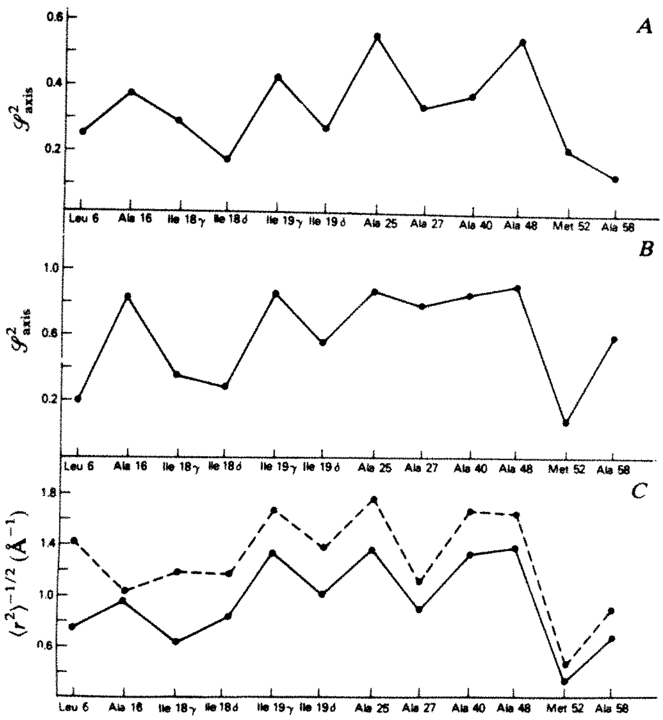

Fig. 1 Comparison of experimental order parameters (*A*) with those calculated from a molecular dynamics simulation (*B*). *C* shows the reciprocals of the theoretical r.m.s. positional fluctuations for the methyl carbons (solid line) and the adjacent heavy atoms (broken line). The experimental order parameters for the δ-carbons of Ile 18 and Ile 19 are based on our assignment of the resonances (see text).

case, independent of the nature of the motion of the symmetry axis, one has[7]

$$\mathcal{S}^2 = \mathcal{S}^2_{\text{axis}}\left(\tfrac{1}{2}(3\cos^2\beta - 1)\right)^2 \qquad (2)$$

where β is the angle between the ^{13}C– H bond and the symmetry axis and $\mathcal{S}_{\text{axis}}$ is the generalized order parameter of the bond joining a methyl carbon and its nearest-neighbour heavy atom. $\mathcal{S}^2_{\text{axis}}$ can be calculated from a trajectory by replacing the average in equation (1) by a time average.

Figure 1*A* shows values of $\mathcal{S}^2_{\text{axis}}$ obtained from the values of $\mathcal{S}^2$ extracted[7] from the experimental relaxation data[9] using equation (2) with the value of β (69.8°) determined from a neutron diffraction study[11] of alanine. The experimental relaxation parameters for Ala 16 and Ala 40 are average values because these resonances were not resolved (we used the same order parameters for these two residues). The δ-carbon resonances of Ile 18 and Ile 19 could be identified (resonances *a* and *b*) but were not assigned[9]. In constructing Fig. 1*A* we assigned resonance *a* to the Ile 18 δ-carbon so that the relative ordering of $\mathcal{S}^2_{\text{axis}}$ of the δ-carbons of Ile 18 and Ile 19 agrees with the simulation (Fig. 1*B*). Figure 1*B* shows the values of $\mathcal{S}^2_{\text{axis}}$ calculated from a 96-ps trajectory of PTI[8]. With the exceptions of Met 52 and Leu 6, the theoretical order parameters are larger than the experimental ones, indicating that there is usually less motional averaging in the 96-ps simulation than detected in the experiment. Such behaviour will occur when the length of the trajectory is too short for a bond to assume all accessible orientations. If there are activation barriers between various conformations, the time required for a single computer simulation to develop an equilibrium distribution of bond orientations will probably be longer than 100 ps (that is, the trajectory can be trapped in a local minimum). The very small order parameter (0.069) for the S—C$^\epsilon$ bond of Met 52 calculated from the trajectory seems to be due to the neglect of solvent effects in the simulation. Recently, it has been shown[5] that the inclusion of solvent leads to a dramatic reduction of the average of r.m.s. displacements of Met 52. Based on the experimental order parameters, we conclude that the motion of the C$^\alpha$—C$^\beta$ bond of Ala 58 is the least restricted of all the residues studied. According to the theoretical order parameters, however, Ala 58 is the most mobile only among the alanines. It is possible that the experimental order parameter of Ala 58 is inaccurate as it is based on only two measured relaxation parameters whereas the other order parameters, with the exception of those of Ala 16 and 40, are based on three. Although differences do exist, it can be seen from Fig. 1*A*, *B* that the relative flexibility of the residues is well described in the simulation. For example, the relative mobilities of all the alanines ($58 > 40 \simeq 27 \simeq 16 > 25 \simeq 48$) is predicted correctly.

Using the model-free approach, an order parameter of 0.87 was extracted from the relaxation data for the α-carbon envelope of PTI. This order parameter, determined by the reorientation of the C$^\alpha$—H vectors, is a measure of the average local flexibility of the backbone. Since to a first approximation the C$^\alpha$—C$^\beta$ bonds are expected to move like the C$^\alpha$—H vectors, we evaluated the order parameters of the C$^\alpha$—C$^\beta$ axis for all protonated α-carbons in PTI. The average was 0.84, very close to the experimental value. Note, however, that the experiment indicates that the α-carbons of alanines move more than the average of all the α-carbons (that is, $\bar{\mathcal{S}}^2_{\text{axis}} = 0.39$ which is less than 0.87) whereas the molecular dynamics predicts that the motion of the alanines is close to the average (that is, $\bar{\mathcal{S}}^2_{\text{axis}} = 0.81$ as opposed to 0.84).

Finally, it is of interest to compare the pattern of the values of the order parameter to the trends of isotropic r.m.s. displacements from the average atomic positions for a series of residues. As $\mathcal{S}^2_{\text{axis}}$ depends on the concerted motions of two nuclei, in Fig. 1*C* we show the reciprocals of the r.m.s. displacements of both the methyl carbons and their nearest neighbours calculated from the 96-ps trajectory. We have plotted the reciprocals to facilitate a visual comparison with the order parameters. In general, there need not be a simple connection between the ordering of $\mathcal{S}^2$ and the r.m.s. fluctuations as these quantities reflect motional flexibility in different ways. For example, although the calculated order parameters of Ala 16 and 40 are almost the same, the r.m.s. fluctuations of Ala 16 are greater than those of Ala 40. Nevertheless, by comparing Fig. 1*B* and *C* it can be seen that there exist many similarities between the pictures of the relative mobility of residues in a protein derived from order parameters and those derived from r.m.s. fluctuations (for example, Ile 18 is more mobile than Ile 19, and Ala 27 is more mobile than Ala 25 by both criteria).

We have described a novel means of testing molecular dynamics simulations where properties related to motions about individual bonds are compared with their experimental counterparts. To our knowledge, this is the first time that the results of a simulation have been related to observable properties at this level of detail. As more experimental data become available on a variety of protein systems, our approach should prove useful in assessing the range of validity of molecular dynamics simulations.

We thank M. Karplus for useful comments on the manuscript and M. Karplus, A. McCammon and J. Ramsdell for the trajectory. G. L. was supported in part by USPHS grant HL 21483 awarded to F.R.N. Gurd, and thanks the Foundation Stiftelsen Blanceflor Boncompagni-Ludovisi, född Bildt for a grant. R. M. L. is an Alfred P. MATTERS ARISING

Simulating silicate structures and structural chemistry of pyroxenoids

CATLOW *ET AL.*[1] have recently described a way of calculating lattice energies of different silicate structures in an attempt to predict which single-chain silicate structure would be the most stable for a particular metal cation or for a particular pair of cations. The stabilization energy (the difference of lattice energies calculated) of one structure with respect to another is often a very small fraction (~0.1%) of the total lattice energy (calculated per Si atom) and therefore a considerable degree of confidence in the values calculated is required.

The essentially ionic model presented has an empirical correction for 'short-range' interaction—presumably for orbital overlap or covalency effects. This correction does not appear to take account of the fact that in some cation environments not all oxygen ligands are equivalent; some oxygens are so-called bridging oxygens between silica tetrahedra and some are directly bonded to one Si atom only. Whether the neglect of this variation in short-range interaction is significant enough to cause appreciable error is not clear.

Nevertheless, there are many further tests Catlow *et al.* could make to clarify the quantitative validity of their model. For example, it is misleading to conclude that the most energetically favoured pyroxene or pyroxenoid structure for Mg^{2+} cations is the diopside structure when it is known that a pure Mg pyroxene has an ortho- or clino-enstatite structure and not a diopside structure. A lattice energy calculation for Mg^{2+} in an ortho- or clino-enstatite structure should therefore show that the latter structures are more stable than the diopside one. (The same argument applies to Fe^{2+}.)

However, the most intriguing point is whether such lattice energy calculations are refined enough to predict cation ordering correctly in such silicates. There is now enough experimental evidence of cation ordering (or the lack of it) in olivines and pyroxenes to provide a testing ground for such calculations. Traditionally explanations of cation ordering have been on the basis of ionic size or, in the case of transition metals, in terms of crystal field stabilization effects. Such explanations are sometimes the result of hindsight and are often less than convincing; sometimes they fail altogether. Clearly therefore it would be very useful to be able to carry out an energy calculation from first principles. Such calculations ought then to be able to predict for example that Fe^{2+} is not ordered in the olivine structure but that Mn^{2+} has a strong preference for the M_2 site—putting Mn^{2+} in the M_2 site rather than the M_1 site should lead to greater stability whereas no appreciable stabilization should occur for Fe^{2+}.

Catlow *et al.* show that the effect of having mixed cations often has a stabilization effect on a particular structure. However, the maximum stabilization will, of course, only be achieved if the correct distribution of cations among the possible sites is chosen. Calculations with different cation distributions should therefore predict the correct one.

G. WALKER

Pure and Applied Physics Department,
UMIST,
Manchester M60 1QD, UK

1. Catlow, C R. A., Thomas, J M., Parker, S C. & Jefferson, D A. *Nature* **295**, 658–662 (1982)

CATLOW AND PARKER REPLY—The comments of Walker on our simulation study of pyroxenoids raise two issues. First, what is the 'accuracy' of the calculated lattice energies; second, what further tests of our method are possible. Regarding the question of accuracy we stress that the methods used by our calculations are exact; there are no errors (above the level of machine accuracy) attributable to our lattice summation techniques. Any 'inaccuracy' arises from inadequacies in our interatomic potentials. Here we note that our potentials perform well in predicting structures of the type of mineral discussed in our article, which supports their reliability in a study of structure discrimination. Moreover, we note that the differences between the energies of different structures are appreciable (that is ~1 eV). The fact that these are a small proportion of the total energy does not mean that they are insignificant; indeed the total energy contains large terms which are relatively insensitive to the structure. The position here is analogous to that in quantum mechanical studies of the energies of small molecules, where binding energies, although a small proportion of the total energy may, nevertheless, be reliably calculated. The point raised by Walker concerning the possibility of different potential parameters for bridging and non-bridging oxygen atoms is valid. However, the success of our calculations in accurately predicting structures suggests that this is not a major effect, although refinements of our potentials should clearly take this effect into account.

As further tests of our calculations Walker suggests first that we examine the enstatite structure of $MgSiO_3$ which he correctly remarks is the most stable structure of this phase. Such calculations are indeed in progress; and our results find that the enstatite structure is more stable than the diopside structure for $MgSiO_3$ and $FeSiO_3$; further details of these calculations will be reported shortly. Walker also suggests that we use our techniques to tackle problems relating to cation ordering. It was indeed with the longer-term view of investigating such problems, that we originally developed our simulation methods. The success of our work encourages the extension to the problems discussed by Walker, although we emphasize that the computational demands of such work are considerable.

Finally, we should point out that the calculations we reported had the main aim of investigating whether energy minimization techniques could usefully be applied to silicate structural chemistry. We believe that our work established the viability of the technique in this field. Subsequent studies will aim at refining our potential models and hence the accuracy of our predictions.

Chemi-ionization in acetylene flames

EVIDENCE has been presented by Hayhurst and Jones[1] in favour of the preponderance of the reaction

$$CH^* + C_2H_2 \rightarrow C_3H_3^+ + e^-$$

over the reaction

$$CH + O \rightarrow CHO^+ + e^-$$

as the primary ionization process in rich acetylene/oxygen flames. This evidence is: (1) low relative concentration of CHO^+, particularly in the reaction zone; (2) double-peaked profile of $C_3H_3^+$ in rich C_2H_2/O_2 flames; (3) double-peaked profile of total ion current in rich C_2H_2/O_2 flames.

All these features may, however, be explained by a mechanism based on CHO^+ alone. It has been realized since the earliest work on mass spectroscopy of flame ions[2] that rapid proton transfer reactions will deplete CHO^+ in flames so that its concentration relative to prominent ions such as H_3O^+ (from protonation of water) will be low. Computer simulations of the kinetics of a simple proton transfer scheme have shown that CHO^+, although the primary ion, will be removed by reaction with H_2O in 10^{-6}–10^{-5} s (ref. 3). The double-peaked feature in the profile of $C_3H_3^+$ is also produced by computer simulation of the scheme:

$$CHO^+ + H_2O = H_3O^+ + CO \qquad (1)$$
$$k_f = 2.5 \times 10^{-9} \quad cm^3\,s^{-1}$$
$$k_r = 5.6 \times 10^{-13} \quad cm^3\,s^{-1}$$

$$CHO^+ + C_3H_2 = C_3H_3^+ + CO \qquad (2)$$
$$k_f = 10^{-9} \quad cm^3\,s^{-1}$$
$$k_r = 1.8 \times 10^{-18} \quad cm^3\,s^{-1}$$

$$H_3O^+ + C_3H_2 = C_3H_3^+ + H_2O \qquad (3)$$
$$k_f = 10^{-9} \quad cm^3\,s^{-1}$$
$$k_r = 4 \times 10^{-15} \quad cm^3\,s^{-1}$$

in which the concentration of C_3H_2, of the order of 10^{-6} mol fraction, is made to follow a double-peaked profile. Reaction (2) was first suggested by Hayhurst and Kittleson[4]. C_3H_2 is an entity about which little is known beyond theoretical calculations of heat of formation, which indicate that it may have a high proton affinity[5,6]. If it occurs in the reaction zones of acetylene flames in association with CH, it may well also recur in the downstream feather described by Hayhurst and Jones, in association with CH and polyacetylene molecules. Furthermore, there are several ion/molecule reactions involving acetylene and other hydrocarbons which produce $C_3H_3^+$ (ref. 7).

Finally, the double-peaked profile for the total ion current could be due to a fresh downstream production of CHO^+ (from CH generated in the 'feather') which would then rapidly generate $C_3H_3^+$ by the mechanism described above.

These points demonstrate the difficulty of finding proof of one mechanism of flame ionization as opposed to another, and the need fully to recognize alternatives in the interpretation of experimental results.

HAYHURST AND JONES REPLY—We accept "the need fully to recognize alternatives in the interpretation of experimental results" and in this spirit suggested[1] that

$$CH^* + C_2H_2 \rightarrow C_3H_3^+ + e^- \qquad (2)$$

produces ions in addition to the well-established process:

$$CH + O \rightarrow CHO^+ + e^- \qquad (1)$$

in very fuel-rich oxy-acetylene flames. Our proposal is based primarily on one piece of evidence, that the profile of total positive ion concentration along such a flame's axis displays two maxima. This indicates that there are two spatially separated regions of ion production. McAllister's explanation of this observation is based on both C_3H_2 and ground state CH having double-peaked profiles. The available evidence[2,3] indicates that the concentrations of C_xH_y intermediates in these flames show only one maximum. In any event, McAllister's scheme involving C_3H_2 is not the only route[4,5] from CHO^+ to $C_3H_3^+$ and does not address itself to the generation of ions from neutrals.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature.* The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 500 words and the briefest of replies, to the effect that a point is taken, should be considered.

Little quantitative information is available on neutral species in these fuel-rich flames. However, it is known[6] that the concentration of oxygen atoms is low in the reaction zone and rises to a maximum just before the end of the feather, that is, close to the second maximum in the rate of production of ions, which we attribute[1] to reaction (1). It is likely[3] that ground state CH displays one maximum in its concentration somewhere in the feather, but its exact location is not known. Electronically excited CH is possibly unusual[6] in displaying two concentration maxima—one where the rate of ion production first maximizes and another farther downstream in the feather. Such complications no doubt derive from CH* being produced[3] by $C_2 + OH \rightarrow CH^* + CO$. The concentration of C_2H_2 declines[6] steadily through the feather. It is thus clear that the product $[CH^*][C_2H_2]$ has a maximum in the reaction zone, whereas [CH] [O] has one farther downstream. This is in line with our suggestion[1] that the first ions are produced by reaction (2), but subsequent ones are generated by reaction (1).

The area of any disagreement thus centres on the process responsible for the original ions in the reaction zone of one of these fuel-rich flames of C_2H_2. Notably, only one oxygenated ion ($C_2H_3O^+$, probably protonated ketene) is detected in the reaction zone. The main positive ion is $C_3H_3^+$ and in fact all the other ions have the formula $C_xH_y^+$. The apparent absence of oxygenated ions, such as H_3O^+ and CHO^+, suggests that the reactions proceeding in the reaction zone and early part of the feather are largely the pyrolysis of hydrocarbon molecules and radicals, rather than their oxidation, which occurs further downstream[7]. This agrees with the observation[6] that oxygen atoms have low concentrations in the reaction zone.

The ratio of the rates of reactions (1) and (2) is $k_1[CH]\,[O]/k_2[CH^*]\,[C_2H_2]$. The value of k_1/k_2 can be estimated to be around unity. [CH*] is much higher than expected on thermodynamic grounds[3] and can be expected to have a mol fraction in these reaction zones of $\sim 10^{-8}$. Mol fractions of 0.1 and 10^{-4} can be estimated for C_2H_2 and CH, respectively. This means that for reaction (1) to dominate reaction (2) in the first production of ions, oxygen atoms must have a mol fraction exceeding 10^{-5}, which is most unlikely[8]. Alternatively, the initial rate of production of ions is measured from our[1] Fig. 1 to be around 3×10^{14} ions $ml^{-1}\,s^{-1}$. If only reaction (2) operates, then the above [CH*] and $[C_2H_2]$ indicate $k_2 \sim 3 \times 10^{-13}$ ml per ion per s, which is entirely reasonable. Note that k_1 has been measured[9] to be 2.8×10^{-13} ml per ion per s at the similar temperature of 2,200 K.

Of course, the above discussion in favour of reaction (2) does not prove that it operates. It does indicate, however, that reaction (2) must be taken as a serious possibility in fuel-rich acetylene flames, where conditions are most favourable for it.

ANNOUNCEMENTS

Appointments

His Royal Highness The Prince of Wales has been elected to Honorary Fellowship of The Institution of Electrical Engineers.

Two appointments have been made at Queen's University, Belfast, **Dr John Blakeman** has been elected to the Chair of Mycology and Plant Pathology, and **Mr Anthony Valentine** has been appointed to the Chair of Paediatric and Preventive Dentistry.

Dr Bruce A. Reitz, a Stanford University National Science Foundation will take up the position of Chancellor of the College Park campus of the University of Maryland, USA.

Dr Bruce A. Reitz, a Standord University heart surgeon, will become professor and director of the Division of Cardiac Surgery at The Johns Hopkins School of Medicine, Baltimore, USA and cardiac surgeon in charge at The Johns Hopkins Hospital.

Douglas A. Fenderson, director of continuing medical education at the University of Minnesota, has been appointed director of the National Institute for Handicapped Research, USA.

Action on Smoking and Health (ASH) announced that **Professor Peter Sleight,** Field Marshal Alexander Professor of Cardiovascular Medicine at Oxford University, has been appointed its new Chairman.

Dr P W Allen, Assistant to the Director, Malaysian Rubber Producers' Research Association, has been appointed Secretary of the International Rubber Research and Development Board UK.

Dr W. Rizk has been appointed Chairman of the Board of The British Standards Institutions (BSI). He succeeds Mr Paul Fletcher who has retired after completing a three year period of office.

Professor Yadin Dudai has been named first incumbent of the Michael and Sara Sela chair in Neurobiology, recently established at the Weizmann Institute.

Dr Robert Lickley has been elected into Honorary Fellowship of the Institution of Mechanical Engineers.

Maximilian Buja, professor of pathology at The University of Texas Health Science Center at Dallas USA was named the first A.J. Gill Professor of Pathology at the health science center.

The Open University has appointed **Roger Mills** as director of its London regional office.

Awards

The Serono Prize in Steroid Endocrinology for 1982 was presented to **Mr Aristidis Slavakis**, a Greek student, on the MSc Course in Steroid Endocrinology at Leeds University, UK.

The British Society of Rheology has made its Annual Award for 1982 to **Professor F.M. Leslie** of the University of Strathclyde in recognition of his contributions towards an understanding of the rheology of liquid crystals.

Dr Karl Frank Austen, of Harvard Medical School, USA, and **Dr Bengt Ingemar Samuelsson** of the Karolinska Institute in Stockholm, Sweden have been selected to receive the 1982 Waterford Biomedical Science Award for their work in allergy and inflammation.

The international award in the BP Energy Research Prize competition has been awarded to **Dr R.P. Howson,** department of physics, Loughborough University of Technology, for his project on selective optical coatings on plastic sheets.

Mr David Attenborough has been awarded the 1981 Kalinga Prize for the Popularization of Science jointly with **Mr D. Flanagan,** editor of *Scientific American.* The award was established by UNESCO in 1951 by means of a grant from the Kalinga Foundation Trust.

Professor H.H. Hopkins, Professor of Applied Optics in the University of Reading, has been awarded the 1982 Gold Medal of the International Society for Optical Engineering for his contributions spanning a broad range of theoretical and applied optical disciplines.

Engelhard Corporation of Iselin, New Jersey USA has been presented with the Council of Environmental Quality's first 'Award of the Decade' for environmental innovation and achievement by American industry. Engelhard was also cited by the United Nations for its contributions to environmental protection.

The Science and Engineering Research Council (SERC) has awarded a special grant of £350,700 for the study of transport and kinetic processes in fixed catalytic reactors. This work, to be undertaken by **Prof. C. McGreavy** (University of Leeds) and **Prof. W.J. Thomas** (University of Bath), is expected to lead to improvements in the design of catalytic reactors.

Whatman Reeve Angel Plc, of Maidstone, Kent, UK., who produce Laboratory Filter and chromatographic Media, are the winners of the 1982 Sedgwick Safety Award for the South East Region.

The Paul-Martini-Prize, founded in order to promote the development of scientific methods for evaluation in the clinical-pharmacological and therapeutical field, was shared 1982 by three German Scientists — **Prof. Dr Gustav Georg Belz** of the Institut for Kardiovaskuläre Therapie in Weisbaden, **Dr Wittich Doering** of the II. Medizinische Klinik des Krankenhauses München-SChwabing and **Dr Jürgen Eberhard Scherberich,** Zentrum der Inneren Medizin at the Klinikum der Johnann Wolfgang-Goethe-Universität, Frankfurt.

The Wellcome Trust has announced the 10 new awards of Wellcome Trust Senior Lecturerships; **Dr Jenefer M. Blackwell,** Ross Institute of Tropical Hygiene, London School of Hygiene & Tropical Medicine; **Dr S.G. Cull-Candy,** Department of Pharmacology, University College London; **Dr P.M. Dean,** Department of Pharmacology, University of Cambridge; **Dr Jean Golding,** Department of Child Health, University of Bristol; **Dr D.J. Harvey,** Department of Pharmacology, University of Oxford; **Dr R.F. Hess, The Physiological Laboratory, University of Cambridge; Dr Hazel C. Jones,** Department of Zoology, University of Hull; **Dr M.C. Sheppard,** Department of Medicine, University of Birmingham; **Dr D.G. Thompson,** Medical Unit, The London Hospital Medical College; **Dr H.V. Wheal,** Department of Neurophysiology, University of Southampton.

The prizewinners of the Feldberg Foundation awards for 1982 are **Professor D. Oesterhelt,** of the Max Planck Institute for Biochemistry, Munich Germany and **Dr G. Radda** of the Department of Biochemistry, University of Oxford, UK. The Feldberg Foundation for German-English Scientific Exchange aims to promote Anglo-German friendship in the medical and biological sciences.

John H. Warden of the Water Research Centre, Stevenage, UK has been awarded the major share of this year's $10,000 Chemviron Award for environmental improvement. Other winners are two professors from the University of Hanover in Germany, **Dr H. Ruffer and Mr T. Slokman.**

Pfizer Central Research have announced that they will make up to six new awards annually of £1,500 each to support young scientists who have carried out meritorious research at British Universities. The work should have potential application in the search for new human or animal health drugs. Two awards will be made available for research in Organic Chemistry, two in Biology, one in Pharmaceutical Sciences and one in Veterinary Research. Further details from: Miss M. Kitney, Pfizer Ltd., Sandwich, Kent. CT13 9NJ, UK.

Entries are invited for a competition to design and construct a voice-controlled robot. The British Computer Society is running a Voice-Controlled Robot Competition is aimed at technicians following TEC HC/HD courses in colleges and polytechnics. The competition is being organized in two stages. Stage one involves production of plans by the end of December 1982. Six designs will then be selected for construction in the second stage, which will conclude in July 1983.

BP PLC, the largest British oil company, has provided the Royal Society, UK with the sum of £30,000 for expenditure over the next twelve months on awards to enable Chinese and British scientists to work side by side, either in joint research projects, or for visits in either direction associated with scientific discussions or seminars, contributing to Sino-British scientific interchange.

Applications are invited for the Rolex Awards for Enterprise 1984. Projects must display a true spirit of enterprise, and fall into the categories of Applied Sciences and Invention, Exploration and Discovery or The Environment. There are five prizes, each of 50,000 Swiss Francs and a gold Rolex chronometer. Application forms from: The Secretariat, The Rolex Awards for Enterprise, PO Box 178, 1211 Geneva 26, Switzerland, before 31 March 1983.

Meetings

3-24 January, **Training Course on Molecular Aspects of Developmental Biology,** Puerto Rico (B.C. Candelas, Dept of Biology, University of Puerto Rico, Rio Piedras, Puerto Rico 00931, USA).

17-20 January, **The Biology and Biochemistry of Cellular Interactions,** Siena (Dr C. Ceccarini, Centro Ricerche, ISVT Sclavo, Via Fiorentina 1, 53100 Siena, Italy).

17-21 January, **Advances in Gene Technology: Molecular Genetics of Plants and Animals,** Miami (Miami Winter Symposium, PMBA Conference, PO Box 016129, Miami, Florida 33101 USA).

20 January, **Institution of Mining and Metallurgy,** London (The Institution of Mining and Metallurgy, 44 Portland Place, London W1N 4BR, UK).

28 January, **The Challenger Society,** London (The Challenger Society, Institute of Oceanographic Sciences, Wormley, Godalming, Surrey. GU8 5UB, UK).

22-24 November. The, meeting on **Cytopathology of Parasitic Disease** is to be held in Caracas, not London as stated in 7 October issue, (The Ciba Foundation, 41 Portland Place, London W1, UK.)

14-18 February, **Safety Training Programme,** Loughborough (The Centre for Extension Studies (KG), Loughborough University, Loughborough, Leics LE11 3TU, UK).

18-23 February, **Chemtech and ORT '83 Exhibition and Conference,** India (Chemtech Secretariat, 210, Dr D.N.Road, Bombay 400 001, India).

22-23 February, **Conference on Cleaner Technologies,** London (Miss Lesley Claff, Oyez Scientific and Technical Services Ltd., Bath House (3rd Floor), 56 Holborn Viaduct, London EC1A 2EX, UK).

21-22 March, **Actions and Interactions of GABA and Benzodiazepines,** London (Mrs Joan Kruger, Department of Pharmacology, University Collge, Gower Street, London WC1E 6BT, UK).

26-30 March, **Eighteenth International Symposium on Computer Applications in the Mineral Industries,** London (The Conference Office, Institution of Mining and Metallurgy, 44 Portland Place, London W1N 4BR, UK).

27-30 March, **First European Symposium on Radiopharmacy and Radiopharmaceuticals,** Elanore, Denmark (Isotope Pharmacy, Frederikssundsvej 378. DK 2700 Copenhagen, Bronsho, Denmark.

28-31 March, **Low Energy Ion Beams,** Loughborough (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

30-31 March, **Universities Federation Animal Welfare/Laboratory Animal Science Association Joint Symposium,** London (Dr H.B. Waynforth, The Animal Unit, Charing Cross Hospital Medical School, St Dunstan's Road, London W6 8RP, UK).

10-17 April, **Environment Impact Assessment Symposium,** Crete (PADC Environmental Impact Assessment and Planning Unit, Department of Geography, University of Aberdeen, Aberdeen, Scotland, UK).

11-13 April, **Annual Chemical Congress,** Lancaster (Dr J.F. Gibson, The Royal Society of Chemistry, Burlington House, London W1V 0BN, UK).

11-15 April, **Symposium on European Rocket and Balloon Programmes and related research,** Interlaken (The Secretariat for the Programme Advisory Committee on the ESRANGE Special Project, European Space Agency, D/OPS-HQ, 8/10 rue Mario Nikis, 75738 Paris Cedex 15, France).

12-15 April, **Conference on Stabilisation and Disinfection of Sewage Sludge,** Manchester. (Mr E. Porter, Water Research Centre, Communications Group, Medmenham Laboratory, PO Box 16, Henley Road, Marlow, Bucks SL7 2HD, UK).

12-15 April, **Electrostatics Conference,** Oxford (The Static Electrification Group, The Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

13-15 April, **Static Electrification,** Oxford (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1X 1QX, UK).

14-15 April, **British Institute of Radiology's Annual Congress and Scientific Exhibition,** London (British Institute of Radiology, 36 Portland Place, London W1N 3DG, UK).

13-15 April, **International Colloquium on Diatomic Molecules,** Oxford (W.G. Richards, Physical Chemistry Laboratory, South Parks Road, Oxford OX1 3QZ, UK).

17-19 April, **Symposium on Aquatic Toxicology,** Milwaukee (M.B. Cooper, 1916 Race Street, Philadelphia, Pennsylvania 19103, USA).

18-19 April, **Symposium on the Determination of Radionuclides in Environmental and Biological Materials,** Teddington (Mr B.S. Marshall, Laboratory of the Government Chemist, Cornwall House, Stamford Street, London SE1 9NQ, UK).

18-20 April, **Intramolecular Kinetics,** Warwick (Prof. J.P. Simons, Department of Chemistry, University of Nottingham, University Park, Nottingham NG7 2RD, UK).

18-22 April, **6th Tandem Conference,** Chester (Mrs S.A. Lowndes, Science and Engineering Research Council, Daresbury Laboratory, Warrington, Cheshire WA4 4AD, UK).

19-21 April, **International Workshop for Atmospheric Spectroscopy,** Oxfordshire (Dr R.W. Saunders (IWAS), Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, UK).

19-21 April, **Physical Modelling of Multi-Phase Flow,** Coventry (The Organising Secretary, Physical Modelling of Multiphase Flow, BHRA Fluid Engineering, Cranfield, Bedfore MK43 0AJ, UK).

19-23 April, **Energy '83,** Hamburg (Hamburg Messe und Congress GmbH, Jungiusstrasse 13 Messenhaus, Postfach 3023 60, D-2000 Hamburg 36, Germany).

26-28 April, **Biologic Diagnosis and Treatment of Malignacies,** Geneva (Dr. W. Hennessen, Scientific Secretary of IABS, Willadingweg 37, CH-3006 Ben, Switzerland).

23-28 April, **The Science of Biological Specimen Preparation for Microscopy and Microanalysis,** Traverse City (Om Johari, Director, SEM Meetings, PO Box 66507, AMF O'Hare, IL 60666, USA).

24-30 April, **Euchem Conference,** Lucerene (Professor J.E. Baldwin, Dyson Perrins Laboratory, South Parks Road, Oxford OX1 3QY, UK).

25 April-1 July, **Understanding Climte Course,** Norwich (Dr T.M.L. Wigley, Climatic Research Unit, University of East Anglia, Norwich, NR4 7TJ, UK).

27-30 April, **3rd Sitges Conference on Protein Nucleic Acid Interactions,** Sitges (Prof. J.A. Subirana, Escuela T.S. Ingenieros Industriales, Diagonal, 647, Barcelona (28), Spain).

What Mr Andropov should do for science

Mr Leonid Brezhnev's death, and Mr Yuri Andropov's succession as the fifth holder of his party post since the Revolution, is also an opportunity for reforming the framework of Soviet science.

For the next few days, Mr Yuri Andropov will have a great deal on his mind. His first need, as one recently emerged from the grey uniformity of the Central Committee (Politburo), is to let the world know that he is flesh and blood. Last Monday's funeral oration was a start. Before turning to matters of substance, Mr Andropov will probably also follow other newly appointed national leaders in replacing the holders of posts with which he must work closely by people who are congenial to him. This will for some time be the chief source of interest to those who make a profession of watching the Soviet Union closely. Meanwhile as Andropov must know well enough, the bureaucracy will look after the day to day business for him. Yet eventually his attention must turn to the issues that occupied his predecessor — East-West relations (poor, even with the lifting of the US sanctions against West European allies for alleged transgressions on the Siberian pipeline), the state of the Soviet economy (parlous) and the state of security and the armed services — and the cost thereof. Will Andropov have the wit to escape this arid agenda to tackle the question none of his predecessors since Lenin (Khrushchev may have been a wayward exception) has had time for — the condition of Soviet science? The beneficiaries of such a departure from immediately past precedent would include not merely Andropov himself, his government, the Soviet scientific community and Soviet citizens at large but also the rest of us.

What follows is a recipe for Mr Andropov's inquiry into Soviet science drawn up on the gloomy but realistic assumption that he will have neither the opportunity nor the inclination to follow radical policies on the questions that most sharply divide the Soviet Union from the rest of the world, the important issues of personal liberty within the Soviet state. It is, of course, offensive that Sakharov is still exiled in Gork'ii and that Orlov and the rest are still imprisoned. It is also the equivalent of tying one arm of Soviet science behind its back that the freedom of Soviet scientists to travel abroad is regarded not as an intellectual necessity but as a reward for loyalty, distinction and longevity. (Obituaries in *Pravda* regularly list a deceased's visits to conferences overseas among the other honours that may have been showered on him.) But nobody should expect that these practices can be changed overnight. The supposition that the state can order the lives of ordinary citizens is a hangover from the feudal doctrine that citizens are literally servants of the state. To acknowledge this is not to condone illiberality but merely to acknowledge that even the most enlightened Andropov would have problems on his hands.

Education

Andropov must first pay attention to the educational system, in many ways the best in the world but also the most cumbersome. Primary and secondary education are universal and state-supported. In the decades since the Second World War, Soviet schools have been acclaimed on several counts, not least for the attention that they pay to the teaching of mathematics, science and technology. In the post-Sputnik years, when curriculum developers in the West were looking for ways of improving the practice of teaching school, they found a great deal of help in earlier Soviet innovations. Yet in the Soviet Union as elsewhere, the overriding difficulties are not those of providing buildings or even schools but of recruiting able teachers. The device of segregating pre-teen students with obvious ability into special schools has demographic advantages but runs the risk, especially with the increasing social stratification of Soviet society, that, as in capitalist Britain, the best teachers will be found teaching the sons and daughters of the middle classes. National olympiads in mathematics and the like, coupled with the conviction of village peasants that a bright young person winning a place in some distant special school is a feather in the local community's cap goes some way to redress the balance, but not nearly far enough. Teaching less, for less time, would be a more equitable but also a more beneficial strategy.

American contributors please note

Authors in the United States and Canada are reminded that they should send their manuscripts either direct to London or to the Washington office, whose address is *Nature,* 991 National Press Building, Washington, DC 20045; manuscripts should *not* be sent to New York.

Specialization

Specialization is a more serious problem, especially in tertiary education. Seriously-minded people embarking on a university career cannot even briefly enjoy the sense that the world will soon become their oyster. First degrees take far too long — four or five years is about par for the course. Thereafter, a person might hope to become a *Candidate* in his early thirties and, provided his work is not inconstant, a *Doctor* (of science, or of something else) early in his or her forties. The academic ladder is, as it seems from outside, a device for making sure that sparks of creativity are snuffed out — and for reinforcing respect for the gerontocracy. In the circumstances, the wonder is not that Soviet science tends to be derivative but that so many people have survived the system. Andropov could do worse than begin by asking for an explanation of why the system should be as it is. And why it should not be different.

The organization of Soviet laboratories is another problem. Contrary to naive supposition in the West, Soviet public administration suffers not from being excessively authoritarian but from too meticulous a division of responsibility. Even in the Red Army, military commanders are coupled with political bosses (of whom Mr Brezhnev was once one). Soviet research laboratories universally have two heads, one a scientist, one a commissar. The obvious consequence, that laboratory directors are usually less adventurous then they would be elsewhere, is written in the unglamorous record of recent decades. Paradoxically, this same system seems to allow wild eccentricity occasionally to flourish. T.D. Lysenko's influence in the 1950s would not have been as disastrous if there had not been a succession of laboratory commissars to vouch for his ideological correctness. Andropov should tackle the problem of how the state laboratories are run, and urgently.

Andropov should also worry about the Soviet Academy of Sciences, whose president, A.P. Aleksandrov, was given a place of honour at Monday's funeral orations (after the Minister of Defence, before the ritual worker). Aleksandrov was also a member of the committee that planned the funeral, but inevitably so. The trouble, however, with the academy is that its formal

0028-0836/82/460203-02$01.00

autonomy (academicians elect each other) conflicts with its function as an instrument of the state, with responsibility for administering public laboratories and, within the past year, committed to even more direct responsibility for running industrial research and development. The most obvious defect of this arrangement is that it is too reasonable, snuffing out the inevitable tension there must be between those with an interest in discovery (which is the basis of future industry) and those with an interest in current production.

The problem of the academy, unfortunately for Andropov, is not the last that calls for his attention. As in Britain, but more scandalously, there is too great a separation between civil and defence research. Only in the past few years has the Soviet space programme begun to make a bridge between the strictly secret activities of the army of defence researchers and those who serve the academy's institutes, the universities and the generality of public service. Socially and in economic terms, the relatively lowly status of the Academy of Medical Science (whose president N.N. Blotkin spoke after Aleksandrov at the funeral orations) may be unimportant, but the neglect of the Academy of Agricultural Science (whose president did not speak at all) cannot be irrelevant to Andropov's problems. Is it not time (and would it not be politically convenient) that Soviet citizens should for once be fed decently? Mr Andropov might, without disadvantage, ask the academy whose president was so much honoured on Monday why agricultural research has been so foolishly neglected. He may discover that he, like other comparable leaders, needs a mechanism by which loyal but free-minded scientists can tell him how resources should best be spent.

Unsolicited advice such as this is never welcome and often goes unread, not least by those to whom it is addressed. Others may ask why advice intended to be helpful (but likely to be overlooked) is proferred at all, in the present climate of East-West relations. There are two simple answers, which the West too often overlook. First, if the struggle (an Eastern word) between East and West is ideological, and if nuclear warfare can be avoided, engagement is preferable to detachment. Second, as both sides are fond of saying, science is international. So must not even the West be deprived by the diseconomies of Soviet science? From Artsimovich to Zeld'ovich, the West has profited from those the Soviet system has allowed to flourish: how much has it lost because so many others have been stifled?

West Germany's millstone

The new West German government seems ill prepared to tackle the problems of its universities.

The long-standing legend of the free-floating German student, moving as the fancy takes him from one seat of learning to another, is appealing but no longer a joke. The West German academic system is at serious risk of being crippled by its students, not merely by the huge numbers of them but by their disinclination to distribute themselves among West German universities according to the distribution of qualified teachers. The result is that some places are overwhelmed with students and that others are half empty. In the circumstances, the vision among academic administrators that the impending decline in the teenage population will bring relief is almost certainly an illusion; more probably, the crowded universities will be just as crowded as at present, and the others even emptier.

Everybody knows that freedom of access to higher education is deeply valued in West Germany. It is also understandable that the Social Democrat government, which helped to institutionalize the doctrine of free access with a sequence of legislation going back to 1969, could hardly have set about devising some scheme for telling would-be students where they should study. Even the introduction of the *numerus clausus* in fields such as medicine was regarded by many of its supporters as a betrayal. The new government is not bound by earlier promises, but seems no more willing to make a fight for commonsense. Will it be different after the March elections?

Ambition running cold?

Last week's meeting of the European Science Foundation was a needless disappointment.

The European Science Foundation is a remarkable organization, not a consortium of governments but an organization of publicly supported research agencies and learned academies which have agreed to contribute small (for them) sums of money to common good causes. At the outset, in 1974, there was nevertheless some reason for hoping that this shoestring organization would so command the loyalty of its customers (mostly working scientists), the fidelity of its members and the respect of their sponsors that it would have a chance of growing into an amalgam of a European academy and a grant-making organization. For the time being, however, that prospect had become too distant for comfort and good sense. Last week's general assembly (see page 207) was a poor augury for the future. The foundation has always been careful not to boast about its potential for the future, saying publicly that it had no ambitions to be more than a marginal institution. The message was appealing when it could be disbelieved. What has happened is that the foundation has begun behaving as if it were indeed a marginal institution. Why has this happened?

The temptation is to suppose that the shortage of money that now afflicts the members of the foundation has made them sour, but that is only half the truth. Domestic budgets are an excuse for parsimony, but not the cause of it. The underlying trouble, and the mainspring of the sourness apparently running through last week's meeting in Strasbourg is that the member organizations have become more inward-looking than they were nearly a decade ago. If that were not the case, they would surely have acknowledged the logic of their own laments at the prospect that good causes such as the fellowships and summer-school programme in brain and behaviour research will founder unless somebody finds another sponsor within two years, and have recognized that they had best dig deeper into their own pockets. If such a programme is acknowledged to be worthwhile, and if those who now contribute towards its cost through the European Science Foundation are to be believed when they say that they would contribute to the same programme under a different umbrella, why can they not see that they would be as well served, and the foundation in the process strengthened, if they made Strasbourg the channel for their largesse? The snag seems to be that the mood has changed. A decade ago, people were looking for pan-European institutions. Now they are more conscious of the respect that they can earn on the international scene by being themselves the sources of the small sums of money flowing into international enterprises.

The foundation should nevertheless not despair. Some of its difficulties are procedural — its own cumbersome ways of conducting business, for example, and constitutional problems among its member states, such as that which prevents Austria from contributing honest schillings to other people's running costs. The first of these could and should be removed by means such as those accepted last week, the second suggests that a treaty between governments might after all be preferable to the present clubbiness. The foundation should also seize on the opportunities that now abound for providing the scientific community with an understanding of the changes that are taking place within it. Even relatively simple questions, such as the amounts of money spent on different kinds of science in different countries (once tackled systematically by the Organization for Economic Cooperation and Development) are now neglected. The changing demography of the academic profession throughout Europe, practical questions of the employment of scientists in different states or of the proper relationship between academic research laboratories and industry (the catchword "technology-transfer" applies) could with advantage be taken up. If European organizations are for the time being short of European spirit, the foundation had better find a bread-and-butter role to keep itself alive until the spirit waxes again.

Stanford's hope for heavy boson

Linear machine may give an edge on CERN

Washington

Physicists at the Stanford Linear Accelerator Center are keeping their fingers crossed during the next few weeks while the Office of Management and Budget (OMB) decides on their $44 million request to begin construction of the Stanford Linear Collider (SLC) in fiscal year 1984. Approval would put SLC in the running with CERN's large electron–positron storage ring (LEP) to be the first machine to produce the roughly 90 GeV electron–positron collisions needed to generate the elusive Z° particle.

"If we get that funding," says Burton Richter, director of the SLC project, "we would be ready to turn on in October 1986". The $44 million would be the first instalment of a total of $110 million required for construction on a three-year schedule. LEP is scheduled for completion in late 1987.

Richter admits that the possibility of beating CERN to the punch has helped fuel enthusiasm for SLC. That enthusiasm seems to carry through the physics community and the Department of Energy's high-energy physics office, a broad base of support that may help the proposal over the twin hurdles of OMB and Congress. OMB's decision will not be made until December, and will not be made public until the President's 1984 budget is released at the end of January. At present, though, indications are that SLC may get the go-ahead. Earlier this year, the Energy Department's High Energy Physics Advisory Panel (HEPAP) strongly endorsed the project, recommending a 1984 start.

William Wallenmeyer, who directs the Energy Department's high-energy physics programme, points out that SLC has already rated "rather high priority"; the 1983 budget provides about $10 million for research and development in connection with the project.

But in its closed-door deliberations, OMB may find several reasons to delay construction. Chief among them is that the physics aspect of SLC — namely the ability to study the Z° — is only a part of the rationale behind the project. Wallenmeyer says the "primary justification" is that SLC would allow a new concept in accelerator design, called the "colliding linac", to be tested. This new breed may prove to be a less expensive alternative to the circular accelerators.

Thus a modest delay in SLC would not harm this primary goal. SLC would be built by adding a loop at the end of Stanford's existing linear electron accelerator. Electrons and positrons would be accelerated down the linear stretch; the electrons would then follow one branch of the loop, positrons the other, and they would collide at the far side of the loop. Energies of up to 50 GeV per beam (100 GeV in the centre of mass in the collision) are anticipated.

Another possible counter to Stanford's push for a 1984 start and a quick three-year construction schedule is that the physics that can actually be done on SLC may in fact be rather limited. George Trilling of Lawrence Berkeley Laboratory chaired a HEPAP subpanel that last January recommended that SLC go ahead in 1984 even under a "low-budget" option — with the savings to come from a cut-back in Brookhaven's ISABELLE accelerator project; yet Trilling says that SLC is "not anywhere on the scale of LEP or ISABELLE; it's of a more limited scope". LEP, he says, will be of general use to high-energy physicists, while the physics on SLC will be limited to the Z° work. And Wallenmeyer points out that the actual discovery of the Z° is likely to come from an existing machine at CERN, which collides proton and antiproton beams. "The purpose of LEP or SLC would be to pursue the resultant physics that comes out of that", Wallenmeyer says. The electron–positron collisions in these machines make the interpretation of decay products much simpler.

None of this, however, discourages Richter in his role as director and chief proponent of SLC. Although SLC will have a single detector as opposed to LEP's four, he says, "SLC has as much physics potential as LEP." Furthermore, he says, SLC will provide a smaller beam (1.4 μm radius compared with LEP's 500 × 50 μm cross-section), making the decay of short-lived particles easier to study; SLC will also be able to generate longitudinally-polarized beams, a boon in attaining high precision in weak-interaction experiments.

Richter also discounts the significance of LEP's higher energy capability. In its current design configuration, LEP will produce energies up to 80 GeV per beam; going beyond that, Richter says, would require a new technology as yet untested. Richter says that once the Z° resonance is reached at what is predicted to be 94 GeV (47 GeV per beam), there is no interesting physics until about 200 GeV (100 GeV per beam), when pairs of charged W^+/W^- particles would begin to be produced in significant quantity.

For all of the build-up, the race between LEP and SLC may be determined in the starting gate if OMB decides to postpone construction of SLC. But if SLC gets the go-ahead for a 1984 start and a three-year construction schedule, it may be a race down to the wire. **Stephen Budiansky**

CERN unafraid of Stanford

Undismayed by the news from Stanford (see accompanying story), the European centre for nuclear research (CERN) is still hoping that it will find the heavy boson in the next few months.

Over the past 4 weeks, CERN's system for colliding protons and antiprotons with each other has been working much better than before. "We are now really in business", said CERN director Professor Herwig Schopper last week. The collisions should produce both the charged intermediate vector bosons, the W^+ and W^-, and the neutral one, the Z°. The collider is working well enough to produce "a few" bosons before Christmas, although it will be difficult to distinguish them from the many other particles produced in the high-energy collisions. The interest in the particles is that their existence is a clear prediction of presently widely accepted unified field theories, so that their detection will provide a critical test of the theories.

Meanwhile, contracts are now being prepared for around a third of the components for the construction of the large electron–positron collider, LEP, which is CERN's next major project. LEP is designed to give the clearest possible investigation of intermediate boson and related physics. The first contracts to be agreed have been for a major section of the 27-km tunnel, for the production of 3.6 million magnet laminations and for steel and concrete cores for the magnets. They have gone to the lowest bidders, which have been consortia involving Italian, French, German, Swiss and Austrian companies. The prices have been roughly as planned, and certainly not low enough, says Schopper, to bring forward the completion date of late 1989.

Construction will not, however, begin until the French authorities give their environmental seal of approval. Two-thirds of LEP lies in France, and one affected village, Echevenex, has made a particularly strong protest (see *Nature* 30 September, p.385). The local review procedure is now over, and CERN must now make its own representations to the committee. CERN has two possible new LEP designs for the Echevenex region. The committee will submit its recommendation to the French government which is expected to come to a decision early next year. **Robert Walgate**

European/Soviet collaboration

Doubts surface

The Committee of the Council of the European Laboratory for Particle Physics (CERN) has failed to reach an agreement on the proposed renewal of its collaboration with the Soviet Union. The Soviet side is anxious for this collaboration to be extended, particularly in view of the construction of CERN's new electron-positron collider (LEP).

The lack of agreement among the committee about the renewal reflected the continuing concern about human rights in the Soviet Union, in particular the continuing repression of such "eminent scientists" as Dr Yurii Orlov and Academician Andrei Sakharov. Since 1978, when Orlov received a 12-year sentence, CERN has taken a special interest in his fate.

The CERN delegates reflect the differing views in the West on how far the human rights issue should be linked to decisions on scientific and trade cooperation. The United Kingdom delegate, for example, expressed a belief in the importance of collaboration in science, saying that Soviet participation in LEP experiments "would be of concrete benefit to the international scientific community", although admitting to concern at the "present record of the Soviet Union in relation to human rights".

The Italian delegation, however, felt that such a sensitive issue should be settled only with the approval of the wider scientific community. They urged, therefore, that a new cooperation protocol be drawn up for ratification by the CERN Council, whose proceedings are public, rather than simply by the committee in closed session.

The machinations of the CERN committee were undoubtedly influenced by the imminence of the Madrid Review Conference of the Helsinki Act, which reopened on 10 November. The CERN Orlov Committee was a co-sponsor, with the Comités Scientifiques Françaises and "Scientists for Sakharov, Orlov and Shcharanskii" (United States), of a special press conference in Madrid, designed to draw attention to the plight of their Soviet colleagues.

The death of Leonid Brezhnev, and the accession to the post of General Secretary of the Communist Party of the Soviet Union of Yurii Andropov will inevitably evoke considerable rethinking of East-West scientific exchange. Although in his funeral oration on Monday, Mr Andropov expressed a commitment to detente and a willingness to cooperate with any country which genuinely sought cooperation, he also pledged support to the "strengthening" of socialist government at home and abroad, which could well lead to actions unacceptable to human rights lobbies in the West. **Vera Rich**

French science research

Papon explains his plans

The Centre National de la Recherche Scientifique (CNRS), the research council which dominates basic science in France, seems to have set off on the right foot with its new director-general, Professor Pierre Papon, who came to the post hot-foot from a political position at the ministry of research and industry in October.

Initially, some feared that Papon's close links with the ministry would increase political influence over fundamental research policy — but his first statement of position to the CNRS council a few days ago confirmed the continuity of his thinking with that of his predecessor, Professor Jean-Jacques Payan, and even hinted that CNRS may influence the government, rather than the reverse.

Papon explained that he had four main objectives to achieve: to create "a new dynamics" in CNRS science; to "open" CNRS to cultural, economic and social needs, and towards the international community and the Third World; to "democratize" decision-making; and to make CNRS "one of the main partners" of the government in the whole process of national science policy-making.

By "new dynamics" Papon means to create new areas of research and to stimulate others — such as general microbiology, or the neurosciences — which are not considered to be at a sufficiently high level in France. Also French science is often strictly compartmentalized, and Papon intends to help break these barriers and induce the movement of ideas and people by setting up new interdisciplinary programmes, such as the programmes on drugs (PIRMED) and materials (PIRMAT).

Papon also wants to loosen the distinction between pure and applied research — although, he insists, "of course CNRS must remain 80 per cent basic". His guiding light is Jean-Frédéric Joliot, the Nobel-laureate radiochemist who was the first director of CNRS in 1944–45. "Joliot thought of applications of radioactivity in the 1930s, when Rutherford was dismissing it as a joke" said Papon. Joliot, although a basic scientist, took out early patents on a primitive radioactive pile. He demonstrated that the pursuit of truth and profit are not incompatible.

As for "opening" CNRS to the outside world, Papon will create two new directorates, one to pursue the application of CNRS results in industry, and one to deal with information, publicity and international relations. Papon, a socialist, stresses his own interest in improving CNRS links with developing countries. But his policy here will be guided by French foreign policy.

The third line of Papon's policy, "democratization", he interprets as "complete transparency": decisions will still be taken by the directorate, but in the open, after wide debate.

The fourth line, making CNRS a partner in government policy-making, means essentially that Papon, with his strong political links and experience, will not hesitate to make positive science political proposals to the minister of research and industry — and other ministers. There will be no waiting meekly for the directives to come from above.

On other issues, Papon is convinced of the value of the 12-year-rule (see *Nature* 14 October, p.569, and 21 October, p.670) by which laboratory directors will have to resign their posts after 12 years in the job; and believes that Dr Maurice Godelier, an anthropologist who a year ago was bitterly opposed as potential director for the social sciences at CNRS, is now broadly acceptable to the social science community "as far as I can tell". Godelier's report on the social sciences in France (see *Nature* 28 October, p.771) is "a masterpiece", according to Papon, and generally agreed to be a good assessment. The appointment of a director for social science and humanities should be made in a few weeks, and although Papon would be happy to work with Godelier he would also accept "any open-minded person" in the job.

On the 12-year-rule, Papon believes it helps to know you have a finite time in which something concrete must be achieved. The only problem is with the smaller groups, set up around one scientist whose ability has been the *raison d'être* of the team. But the rule, as later qualified by the research and industry minister, leaves room for manoeuvre. **Robert Walgate**

Good news for BAS

The Falklands War seems to have worked to the advantage of the British Antarctic Survey. The Department of Education and Science announced last week that it is to allocate an extra £4 million in 1983–84 in addition to the normal allocation expected from the Natural Environment Research Council (NERC). After a long period of tight budgets, this appears to be the beginning of an expanded commitment by the British towards Antarctic research. NERC's allocation to the survey for this year, £7.8 million, is already significantly more than last year's £5.6 million.

No reason was given for last week's announcement, and it is not yet known how the extra money will be spent. The Falkland Islands are used as a refuelling and supply base for Antarctic survey support ships. At present there is a numerically superior Argentinian presence in the Antarctic Peninsula, with 158 Argentines (132 of them military personnel) and 58 British survey scientists. David Millar

European Science Foundation

Living with level funding

Strasbourg

This year's general assembly of the European Science Foundation (ESF), at the European Parliament on 9–10 November, was curiously disappointing. For almost the first time since its creation in 1974, the foundation spent as much time deciding how and when to bring good projects to an end as on the problems of how best to launch new enterprises.

Part of the trouble is that the foundation seems to have been infected with the present preoccupation of its members — all of them research organizations in the member states (which include Jugoslavia, Turkey and Israel as well as countries in Western Europe and Scandinavia) — the problem of living within a constant budget. In this spirit, the assembly spent much of its energy this year wrestling with the question whether one of its first and most successful programmes, the European Training Programme in Brain and Behaviour Research, should be pushed towards independence one, two or three years hence. But the assembly's consideration of new projects has also been strangely flat and uncritical.

The foundation is for practical purposes a club whose members are publicly supported grant-making agencies in the member states. Each national group pays a collective subscription determined by its home state's Gross National Product, but may then contribute voluntarily to the several "additional activities" that make up the foundation's research programme.

In such circumstances, it is hard to tell how large is the effort subsumed under the umbrella of ESF. This year, for example, central expenditure will amount to FF6.8 million (£0.5 million), but cash contributions for additional activities will amount to FF5.7 million and there seems to be a gentlemen's agreement that overhead costs should be concealed wherever possible. The proposal that central expenditure next year should rise to FF8.1 million — rather less than 0.05 per cent of the budgets of its members — was accepted without a trace of dissent, no doubt in gratitude for the foundation's implicit undertaking that from now on it will take on new projects only when it has discarded others.

The counterweight for the proposed abandonment of the brain and behaviour programme is the European Geotraverse project, a plan to mount a series of deep seismic soundings along a north–south band running from northern Norway to Tunisia, together with coordinated geological, geochemical, geomagnetic and magneto-telluric measurements (see *Nature* 29 July, p.413). The project was enthusiastically endorsed by the assembly, or at least by those of its members whose national boundaries lie near to the traverse.

Enthusiasm does not however mean money. The traverse project will require 14 million Swiss francs (£3.75 million) for central funds, while the planners (led by Dr P. Fricker, secretary-general of the Swiss National Science Foundation) hopes that a further FF8 million will be spent by member states on regional studies. In the event, roughly half the countries concerned were able to commit themselves, in a genteel version of a political fund-raising affair, to contribute to the costs of coordinating the enterprise.

In future, the foundation hopes to have a better mechanism for recruiting contributions towards such additional activities, the assembly having adopted at this meeting a set of proposals negotiated by a group under Dr Fricker that will allow interested members' budget contributions to be negotiated while projects are being developed. As things are, members have no cause to dissent in public from proposals they consider to be half-baked, knowing that silent assent need cost them nothing.

For the rest, the assembly reappointed Professor Herbert Curien as president for a further three-year term, heard Sir Hermann Bondi plead for a better understanding and appraisal of environmental problems, agreed that something should be done to improve legislation covering archaeological sites, agreed that similar laws are needed to secure meteorites for science, applauded those of its members seeking to persuade some European government to play host to a European source of synchrotron radiation and approved a plan to hold an interdisciplinary meeting on the criteria for progress in science in whose specification the word "discovery" does not appear. ●

European space research

Backing away from Ariane?

European astronomers, increasingly concerned about the delays in the Ariane rocket programme, are pleading that the European Space Agency (ESA) should consider launching their next X-ray satellite, called EXOSAT, on a Thor-Delta rocket. A decision to switch launchers at this stage would embarrass (but possibly relieve) Arianespace and cause contractual problems (but probably decrease the cost). According to one senior X-ray astronomer, however, the case for switching launchers is now undeniable on scientific grounds.

The three-stage Ariane rocket has failed, for different reasons, on two out of five of its launches. A committee of inquiry has determined that the failure on the last launch was due to problems with lubrication and design tolerances in the rocket's turbopumps. These are being modified before the next launch in April. On present plans EXOSAT would be launched on the following Ariane in the middle of next year.

EXOSAT, the only X-ray astronomy satellite expected to fly for several years, represents a significant investment over the past few years by European astronomers. Several aspects of its design reflect the recent rapid development of X-ray detectors.

The satellite was originally designed to be launched on a Thor-Delta rocket, and the subsequent decision to change to Ariane had a strong political (chauvinistic) element. Accordingly, only minor structural modification would be necessary to go back to a Thor-Delta launcher, which has an enviable record of successful launching.

Now British, German and Dutch astronomers have written to ESA asking that EXOSAT be an urgent item for discussion at the December meeting of the Science Programme Committee and requesting that "all possibilities be considered". Any recommendation made by that committee would have to be ratified by the council of ESA, which would normally place much weight on the programme committee's recommendations.

A Thor-Delta would cost about 10 million accounting units (AU) — about £5.4 million at current prices — less than Ariane but ESA has already paid Arianespace 30 million AU for the EXOSAT launch. Arianespace might, however, be relieved not to have to launch EXOSAT. First, it is under pressure from commercial users to launch their satellites on schedule. Second, the EXOSAT launch would require a hitherto untested fourth stage to be added to Ariane, leading to the increased possibility of another failure.

There are other technical reasons why X-ray astronomers would push hard for a switch. Thus it is possible that a Thor-Delta could be ready in time to launch EXOSAT at the end of the current window. (EXOSAT's orbit is highly elliptical, permitting more extended observations of variable sources and more continuous contact with ground tracking stations than with previous X-ray satellites. The "windows" are those periods in the year during which a launch would provide the appropriate combination of solar cell illumination and the correct location of the orbital apogee in the sky.) With Ariane, this window ends in January, and another launch would not be possible before the middle of next year. The use of a Thor-Rocket, obviating the need of Ariane's transfer orbit, would extend the window to February, giving the possibility of an "early" launch and the avoidance of six months' degeneration of X-ray detectors stored in laboratories. **Philip Campbell**

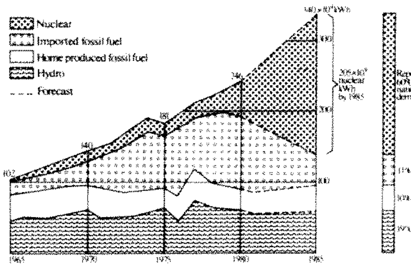
French nuclear power

Testing time for reactors

The problem with French nuclear power stations is that three-quarters of them are less than three years old, and suffering from teething problems, according to Electricité de France (EDF), which owns and runs them.

What is not clear is whether this should be a comforting or a disquieting thought. French nuclear power production is supposed to be increasing, but in September EDF produced only 6,700 GWh of electrical energy, compared with 8,200 GWh a few months previously. The net availability — the proportion of energy delivered to nominal capacity — fell to below 50 per cent in the summer, compared with a typical industry target of 70 per cent and a world average for pressurized water reactors (PWRs) (according to EDF) of 60 per cent. But, says EDF, PWRs more than three years old had the magic 70 per cent availability. It was the young ones — an independent design series of 20 or 50 — that were in trouble.

The accompanying figure reveals how much of the French nuclear power programme is indeed young, coming on line during 1980–85. This is literally a testing time for French nuclear power. Of the 22 reactors now connected to the grid, only 6 were connected before 1980. Seven were connected that year, seven in 1981, and two have been connected this year. However, another 30 are under construction, due to come on line during 1983–89.



Power consumption in France

According to EDF, the problems amount to a combination of technical teething troubles and government safety regulations. There are three issues: a concentration of seven four-month shut-downs for obligatory inspections, after 18 months' operation, compared with four such shut-downs in 1981 and two planned for 1983; and two problems with faulty materials in the younger reactors.

One of these problems is outside the nuclear part of the reactor, in the steam "drier-superheater". This halted two reactors, Saint-Laurent B1 and B2, for a considerable period, but the problem is now thought to have been solved for these reactors and others in their production series.

The more awkward problem is the stress-corrosion cracking of inconel clips holding guide tubes for the control rods within the reactor vessel. The problem was first noted in Japan in 1979, and since then the clips have undergone redesign in French reactors beginning construction. But most reactors coming on line in the past three years have the old clips, and there have been failures and shut-downs this year at Fessenheim 1, Bugey 2 and 4 and Gravelines 1. The clips are to be replaced on a series of 20 reactors, at a net cost, according to EDF, of about FF 1,300 million (£110 million).

But is this the end of the "teething" troubles — or will there be more to come, when the problem, like the clips and the drier-superheaters, will be multiplied through a long production series leading to high replacement costs, and a degree of insecurity in future electricity supply, which is planned to reach 60 per cent nuclear by 1985?

However, this can be taken as an argument for building more nuclear rectors, not less, to provide a cushion of overcapacity, and it will no doubt be taken that way at the ministry of research and industry in the forthcoming argument over coal and nuclear power and falling energy demand forecasts (see *Nature* 11 November, p.100). In Britain, too, where the Central Electricity Generating Board is planning its first PWR at Sizewell, Suffolk, the French problems are seen in a positive light — as useful design lessons. **Robert Walgate**

US defence

Townes in dissent on MX siting

Washington

Controversy continues about how and where the new MX missiles should be based. President Reagan is committed to give Congress a plan for basing the MX (short for "missile experimental") by 1 December and the Secretary of Defense, Mr Caspar Weinberger, has done his part by transmitting his recommendations to the White House, apparently on 1 November. But now his most prominent scientific adviser on the issue, Dr Charles Townes of the University of California at Berkeley, has taken the unusual step of expressing his personal doubts about the now-favourite plan — and the contents of his letter have been promptly leaked in the US press.

The question of how to deploy MX has been a long-standing conundrum. Out of about 30 alternative plans suggested by the military, the Carter Administration selected that called "Racetrack" in which missiles would have been moved from one launching point to another by means of underground tunnels. But by the time the plan was put forward, so many doubts had arisen that Congress never approved it.

The same fate may yet await the Reagan Administration, which has already failed to persuade Congress to authorize funds for deployment — without specifying how the missiles would be deployed. Townes was appointed head of a panel of scientists and defence experts to re-examine the MX problem when Mr Weinberger took office. The scheme now most favoured by the US Air Force and, it is rumoured, by Mr Weinberger is called "Dense Pack". MX missiles would be placed in fixed and hardened canisters in the ground so close together that incoming warheads would interfere with each other, the blast and other consequences of a nuclear explosion interfering with later arrivals.

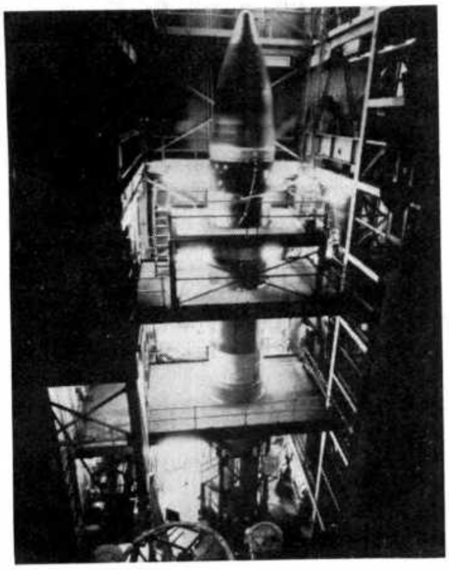
The Air Force now says that 100 MX missiles separated by distances of about 2,000 feet would be close enough to ensure interference (called "fratricide" in the new jargon). Hitherto, the Air Force has discarded Dense Pack on the grounds that missiles not destroyed in an attack would be unable to fly out in retaliation. The new development is that the Air Force says that missile silos can be hardened so that their missiles will survive even if over-pressures amount to 5,000 lb per square inch.

The nub of Townes's argument is that this "super-hardening" may not be feasible, that there are no clear limits on the time that would be needed for such a development or of its cost and that the Soviet Union might find a counter to Dense Pack sooner than the Air Force could install it.

Military considerations apart, Dense Pack has the political advantage that it would occupy an area of only 10–15 square miles. One of the objections to Racetrack from ranchers and environmentalists in western states was that huge tracts of land would be required.

"FRATRICIDE—
HOMICIDE—
SUICIDE—IT'S
ALL THE SAME
TO ME."

The latest version of Dense Pack advocated by the Air Force is that the 100 MX missiles would be sited in a long thin column aligned north to south. This has the theoretical advantage that the optimum pattern of an attack on the missile field from the Soviet Union, called a "walk attack", can be predicted: the most southerly rows of missiles would have to be attacked first and succeeding warheads would have to be aimed at suitable intervals at rows of missile silos sited further north. On this argument, a pattern of attack moving from north to south would be ineffective because later warheads would have to survive the atmospheric disturbance caused by the first nuclear explosion.



It is not clear what the consequences will be for Dr Townes now that his strong expression of personal doubt about the government plan has leaked into the press. Scientific advisers have run into trouble on such grounds on many previous occasions. But Dr Townes is much respected within the present Administration and his opinion may even help the President to reach a wiser decision by the beginning of next month. **Deborah Shapley**

Yes to toxin cloning

Washington

The Recombinant DNA Advisory Committee (RAC) approved two controversial toxin-cloning experiments at its 25 October meeting, but ordered that they be carried out under P4 containment, the most stringent safety precaution available.

Dr John Murphy of Harvard Medical School, who in July 1981 received permission to clone the diphtheria toxin gene in *Escherichia coli* K-12, will now be allowed to extend those experiments to linking the toxic gene with the gene that codes for melanocyte stimulating hormone. The aim is to generate a hybrid toxin molecule that selectively homes in on melanoma cells.

The experiments will have to be performed at the National Cancer Institute's laboratory at Frederick, Maryland, which is the only P4 facility in the country. **Stephen Budiansky**

German research and technology

Waiting for the next election

Bonn

Dr Heinz Riesenhuber, appointed last month as West German federal minister for research and technology, seems to have made a good first impression. But it is also clear that between now and the promised general election next March, there will be time only for some modest if urgent housekeeping, and for planning how to put flesh on the bones of the promises of the past few weeks.

The federal ministry for research and technology has two immediate tasks — to win agreement on a budget for next year (and on a supplementary budget for 1982) within the caretaker government and with the parliament; and to put the two big prototype nuclear reactor projects on a sound financial basis. Both issues must be settled before the year is out, for thereafter all contentious issues will be overtaken by preparations for the election.

The budgetary and reactor issues are closely linked, for the reactor construction costs are a large part of the federal ministry's budget. There seems a good chance that the parliament (Bundestag and Bundesrat) will fall in with the previous government's proposal that the ministry should have a supplementary subvention of DM500 million (£116 million) with which, for practical purposes, to liquidate bank loans taken out by participating electricity utilities to keep construction going. (The propriety of this device could nevertheless become a political issue at the election.) If the Christian Democrat government is re-elected, Dr Riesenhuber's belief that both reactors should be completed will nevertheless become a simplifying touchstone for future policy: although, as one high official emphasized last week, the government will not support the projects "at any price". But the new government seems to understand that new technology is never more expensive than when it is postponed.

The implications of Dr Riesenhuber's first-flush declaration that research and technology must share in the new government's commitments to a six per cent reduction of spending, but that "basic research" must at the same time be protected, are harder to discern. Some officials hope to find some relief from the strictest possible application of the six per cent rule in the *caveat* that it may not apply when the consequences would be legally invalid. Most of the ministry's projects entail agreements with constitutionally autonomous Länder governments for example, and may therefore be exempt. The budget for 1983 now being canvassed in the Bundestag, at just under DM7,000 million, is a reduction of DM300 million on the original budget for 1982 — the first reduction since the ministry's creation in 1971. But it seems to be an article of faith that when economies are decided, they will not affect basic research.

Dr Riesenhuber's other memorable declaration, that the large national research laboratories should have a closer relationship with industry and that direct support for research and development should progressively be replaced by "indirect support", is for the time being equally uncertain in its implications. The minister's conviction that civil servants cannot adequately supervise the more than 6,000 direct-support projects now on his department's books is readily accepted, but nobody has a clear idea of what indirect support consists of. The notion that the federal government might subsidize the salaries of qualified scientists and engineers working for small and medium-sized companies is one being canvassed. By the general election, Dr Riesenhuber may have other cards up his sleeve. Meanwhile, he is committed to the award of a prize of DM30,000 at some point during 1983 to somebody working in a public laboratory making the most outstanding contribution to industry.

No doubt in the hope of avoiding similar problems with thermonuclear fusion, the federal ministry of research is planning to peg its total expenditure on fusion, principally at the Max Planck Institute at Garshing and the JET laboratory at Culham in the United Kingdom, to about DM200 million a year. It has been decided that Garshing will be concerned only with plasma physics machines, and that the nuclear research establishment at Karlsruhe will assume responsibility for any experiments in which thermonuclear fuel is consumed to produce radioactive materials.

Elsewhere, the prospect that a change of government may stimulate other changes seems now, as ever, frustrated by the constitution. Nobody thinks it feasible that the excess numbers of students at the most popular universities could be limited by some selection process, or even arbitrarily; the Länder would not stand for that. The federal ministry of education is nevertheless hoping to help cure the enforced immobility in academic life in the past few years with a proposal to spend DM50 million a year on the appointment of up to 1,000 newly graduated PhDs to one- or two-year posts in universities. This development, valuable in itself, is also a test of the federal government's undivided constitutional responsibility for research. The bill now before the Bundestag does not depend on the compliance of the Länder governments.

The education ministry, following the doctrine that basic research should be protected, has also managed to increase the budget of the Deutsche Forschungsgemeinschaft for next year by four per cent. ●

European Molecular Biology Laboratory

Crucial decisions ahead

Heidelberg

This month is crucial for the European Molecular Biology Laboratory, supported since 1974 by eleven European governmental research agencies, a subset of the seventeen members of the European Molecular Biology Organization. Next week the governing council of the laboratory will decide whether it can match with deutschmarks its acceptance of a new scientific programme at its meeting last June. The director of the laboratory since 1 April, Dr Lennart Philipson, is dismayed by suggestions such as that in the report of the British Advisory Board for the Research Councils (see *Nature* 4 November, p.1) that the Medical Research Council should "review" its membership of the laboratory.

The Medical Research Council refuses to comment on this recommendation. It is however known that its secretary, Sir James Gowans, paid an unofficial visit to the laboratory in September, since when there have been two visits by parties of officials to the laboratory and its two outstations at Hamburg and Grenoble.

Whatever the UK research council's attitude next week, the council meeting is certain to be uncomfortable. Philipson is asking for budget contributions of DM36.7 million (£8.5 million) for 1983, a substantial increase on the total contribution of DM 30.2 million in the present year. Philipson emphasizes, however, that a direct comparison of these figures is misleading. In past years, the laboratory has consistently failed to recruit up to its planned strength, with the result that there has usually been a cushion of unspent appropriations to help with the succeeding year's budget. During the present year, members' contributions have been augmented by more than DM6 million from this source, but for next year there will be a cushion of only DM2 million.

The perplexing question now is whether next week's council will accept that the planned increase in expenditure amounts only to 6 per cent, or whether it will take fright at being asked for a 20 per cent increase in members' contributions.

The more distant but more important question of what the laboratory is for has, however, been settled by the scientific plan agreed in June. The laboratory now accepts that there is no means by which its existence can be justified on grounds comparable with those applicable to international laboratories such as CERN in Geneva. While the synchrotron radiation and neutron diffraction facilities (at Hamburg and Grenoble respectively) are much used, especially by workers from smaller countries, they are not unique. And the prospect that the low-temperature electron microscope developed at the laboratory might be a focus for international collaboration has receded as the predicted resolution of that instrument has decreased (see *Nature* 30 September, p.386).

The new programme entails that the instrumentation division at the laboratory will become a source of new technology in molecular biology for the laboratory and member organizations. The development of the low-temperature electron microscopes will continue, but the excellent workshops will be increasingly used for building prototypes of instruments for which there is a known need.

In molecular biology proper, the laboratory is best known for its work on membrane proteins. On the basis of workshops held earlier this year, it is now planned also to concentrate on two new fields — protein–DNA interactions (as in the functioning of regulatory nuclear proteins) and differentiation (as typified by the haematopoeitic system. Dr Thomas Graf has been recruited from the nearby German Centre for Cancer Research (on a five-year rolling contract) to help develop the second line of inquiry. Meanwhile, the structural group at the laboratory will concentrate on emerging opportunities for the structural analysis of membrane proteins.

The long-term objective is thus to create a recognized centre of excellence, but also more fully to implement the laboratory's brief as a training centre. There will be one summer course next year, and a series of courses between June and September in 1984. Meanwhile, the laboratory is arranging with European universities to recruit up to ten graduate students a year.

The development of the scientific programme is the source of Philipson's immediate difficulties. The laboratory's target payroll of 267 people (excluding visitors) has never been filled, but next year's budget allows for 255 people, a substantial increase on this year. There is also to be a system of external reviews of scientific programmes at intervals of three years.

It seems to be accepted that in its new form the laboratory will be of more immediate value to member organizations too small to sustain substantial molecular biology laboratories of their own. But Philipson says that there is one sense in which Heidelberg is likely to become unique — it has been laid down that scientists on the payroll should not have external links with commercial organizations, although they may work as consultants during vacation time. ●

Industrial sponsorship

Fewer payrolled students

Industrial sponsorship schemes, under which a favoured proportion of Britain's 251,000 undergraduates receive a substantial financial boost from industry, seems to be on the decline. A better understanding of the trend is likely to come from a new research project to be conducted by the Institute of Manpower Studies (IMS) at the University of Sussex.

In some subject areas, notably electrical engineering, as many as 50 per cent of all undergraduates may be sponsored, according to Richard Pearson, head of the IMS Labour Market Studies Group and director of the study. Yet despite the obvious importance of the practice for graduate recruitment patterns in general, there is a striking absence of hard information about figures and trends. Sponsorship may mean up to an extra £800 per year to an undergraduate, and some employers, such as British Telecom, actually reward their favoured potential recruits with a salary while they are still at college. In return, there is a gentleman's agreement that the student will accept any offer of employment from the sponsoring company after graduating. Of undergraduates who started their courses in 1980, 2,000 at universities and nearly 1,000 at polytechnics found an industrial sponsor, mainly in the fields of electrical and mechanical engineering. The IMS study, which is supported by a £55,000 grant from the Leverhulme Trust, will concentrate on sponsorship by individual companies in both public and private sectors.

Most of the sponsorship schemes now operating started in the late 1970s and apply to the general area of engineering, where there was until recently a severe shortage of suitably trained graduates. Up to 50 per cent of all students taking sandwich courses (which include one or more periods of training in industry) are thought to receive some form of sponsorship. Dr Clive Purkiss, director of IMS, has drawn attention to the lack of clear information on which employers can base sponsorship decisions. Although industrial sponsorship may be regarded as being partly a public relations gesture by the sponsoring companies, it does enable them to get an inside track in their graduate recruitment programmes. It may also be the cheapest way of ensuring an adequate training in a specialist discipline, which according to one estimate may otherwise cost up to £75,000 to the age of 25.

The past two years, however, have seen a drop in the number of sponsored places available: British Telecom's total is down slightly this year to 32, and BP Ltd has just axed its scheme altogether According to Professor Ray Wild, of Brunel University's Special Engineering Programme, this is partly because companies have become more selective, preferring now to identify

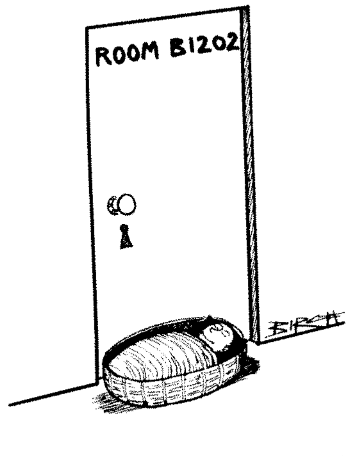
0028-0836/82/460210-02$01 00

potential recruits before they start a degree course rather than to pick them out part of the way through.. The number of students on National Engineering Scholarships (financed jointly by the Department of Education and Science and the Department of Industry) has also been reduced this year, from 300 to around 100. At the same time, educational institutions are trying to increase sponsorship for their students. Some colleges actually specify industrial sponsorship as a requirement for some of their courses, as at London's Imperial College. Students are simply issued with a list of potential sponsors and told to make their own arrangements; the value of the sponsorships on offer varies considerably.

At the moment few small firms sponsor undergraduates, so major employers who run generous schemes can take their pick of the best potential engineers and managers Less well known firms have to compete against household names in the minds of school sixth-formers who have little knowledge of the industry: Brunel University, whose engineering students are all fully sponsored, is organizing a consortium of several groups of small companies to help overcome this difficulty. The IMS research should receive widespread attention, not least from the students themselves. **Tim Beardsley**

Warnock seeks evidence

The chairman of the British government's inquiry into human fertilization, Mrs Mary Warnock, has asked for all interested bodies and individuals to submit evidence before the deadline of 1 March 1983. The enquiry, due to report in 1984 has a broad brief — covering social, ethical, legal and medical aspects of developments in human fertilization including *in vitro* fertilization techniques. Evidence should be submitted to: The Secretary, Inquiry into Human Fertilization and Embryology, Room B1202, Department of Health and Social Security, Alexander Fleming House, London SE1.



UK graduate employment

No jobs for the boys (or girls)

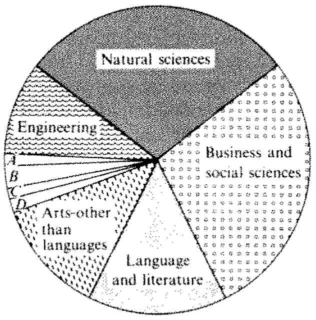
About 15 per cent of this year's crop of first degree graduates from British universities will still be looking for jobs at the end of the year. This gloomy estimate was made by Mr B.E. Steptoe, chairman of the statistics subcommittee of the Association of Graduate Careers Advisory Services; 11.3 per cent of that year's graduates had not found jobs by the end of December. Among polytechnic graduates, the figure is likely to be even worse.

The position of this year's 105,300 new graduates is, of course, made worse by the fact that they are now competing for jobs with those of the 1981 crop still unemployed. As a result, many companies that previously recruited graduates straight from college are now looking for people with some useful work experience. There are also increasing numbers of "underemployed" graduates doing jobs that previously would not have required a degree; some of these will undoubtedly find more suitable employment in time, but a large proportion are likely to remain underemployed.

The trend is described by Mr Brian Putt, director of the Central Services Unit (an advisory body to graduate careers services) as a "disastrous social iceberg". The number of graduates entering the job market will continue to rise by about 2-3 per cent each year at least until 1984, when the effects of last year's cutbacks in higher education places will become apparent.

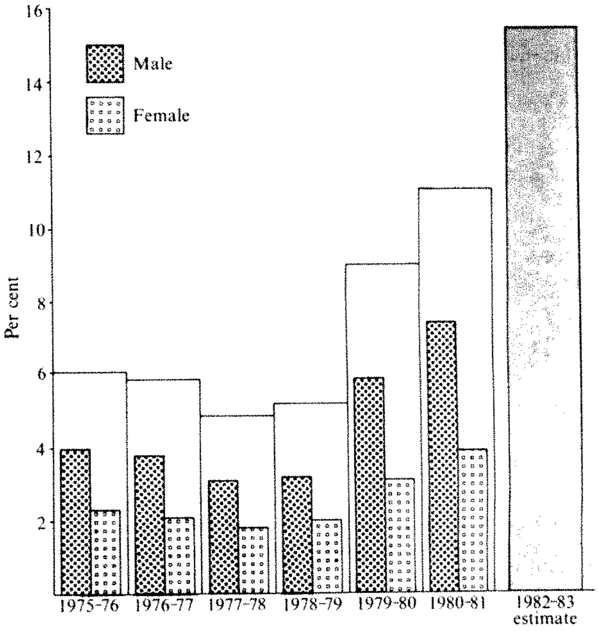
Unemployment continues to be highest amongst those reading arts subjects, and of the sciences biology clearly has the largest proportion unemployed. However, factors such as falling oil prices have had an effect on recruitment even in traditionally "safe" subject areas; some university careers offices have reported problems among civil and mechanical engineers, for example. The number of companies that recruit on the "milk-round" of universities has decreased this year (although the decrease is not large), and there are other indications that the number of advertised vacancies for graduates has fallen over the past two years. The sudden growth in the number of sponsorship schemes since 1979 (see accompanying figure) accounts for a part of this decrease, and it seems that the number of vacancies has probably reached a plateau. It is unlikely to increase significantly for at least 18 months, even if there were to be a major reflation of the economy next year. **Tim Beardsley**

Per cent home first graduates unemployed, shown according to discipline



A Architecture and other professional and vocational studies
B Agriculture, forestry and veterinary science
C Medicine, dentistry and health
D Education

Home first degree graduates believed unemployed at 31 December



All values are expressed as percentages of the total number of graduates of known destinations. About 10 per cent of graduates did not reply to survey questionnaires. The 1982 figure is an informed estimate.

CORRESPONDENCE

Orang is man

Sir — I have long resisted the temptation to point out the erroneous practice of many Western editors and authors of abbreviating 'orang' for 'orang-utan'. Reference to any Malay or Indonesian dictionary will confirm that 'orang' means 'man' and 'orang-utan' means 'orang-utan'. Therefore, when Lowenstein, Molleson and Washburn reported that they have results to prove that 'both the Piltdown jaw and the canine tooth are those of an *orang-utan*' and you have their letter headlined "Piltdown jaw confirmed as orang" (*Nature* 23 September, p.294), I hope you are guilty only of misleading your readers with an inappropriate abbreviation and not of misunderstanding the key issue of the debate!

"IT'S ALL EXPLAINED IN THE THOUGHTS OF CHAIRWOMAN MAO!"
BIRCH

Chinese puzzles

Sir — In *Nature* of 16 September (p.200) J.A. Irving wrote to point out that Chinese surnames precede given names. This is no longer a problem in English translation because given names are now hyphenated and the second one is not capitalized. For foreigners, however, the gender of nouns and pronouns remains confusing. For instance, "Mr" Qi, cited by Irving, is actually Mrs Qi.

War prevention

Sir — Jeffrey Segall (*Nature* 4 November, p.10) attributes to me (*Nature* 7 October, p.482) approval of the Medical Association for the Prevention of War (MAWP) proposals for a "Comprehensive ban on all methods and means of warfare specifically designed to kill or injure by inducing human disease". He fails to see two separate strands in my comments on MAWP.

Firstly, I consider the existing international prohibitions and other restrictions on warfare as among the highest achievements of man. We should all hope for a wider and more effective extension where appropriate of their type of international agreement. However, without diminishing their significance, it should be recognized that their success lies in that they involve noncentral areas of military concern.

Secondly, we should not restrict our attention only to the salient and direct causes of suffering involved in war. The concern with the methods and means of warfare should not distort our perception to ignore the fact that wars are initiated in the pursuit of military and political goals. And that prevention and control of these goals are as significant, if not more so, as that of their means for stopping war and the suffering within them.

Unfortunately not all desirable things are compatible. The inhibition of the initiation of wars depends largely on deterrence which requires armaments. The removal of the world's dependence on deterrence is likely to be achieved not by disarmament but by either an ascendancy of one of the superpowers to be effectively the only world power, or the creation of internal political structures of inhibition within military superpowers. But the latter and most desirable change would require the unlikely development of political pluralism, autonomous judiciary and intellectually open societies in the at present totalitarian powers of the Soviet Union and China.

Malaria resurgence

Sir — Chapin and Wasserstrom[1] stated that resurgence of malaria in India was the result of the introduction of high yielding varieties (HYV) of rice and cotton, and we disputed the basic tenets of this hypothesis[2]. The main thrust of their argument now, however, seems to be that resurgence was the result of the use of insecticides in agriculture[3]. We would like to add a few further comments.

(1) Widespread resistance to common pesticides in anophelines developed during early and mid-1960s. *Anopheles culicifacies* was found resistant to DDT in 271 units in 14 states and to BHC in 24 units in 4 states. Similarly *Anopheles stephensi* was found resistant to DDT in 34 units in 5 states and to BHC in 6 units in 3 states[4].

(2) *A. stephensi* type form, the vector of urban malaria in India, breeds in cisterns, overhead tanks, garden tubs, fountain basins, disused containers, receptacles used for storing water, and other water accumulations in cities and does not breed in agricultural fields. Resurgence of malaria was observed in cities of India from southern, central and north India[5].

(3) Although accurate quantities of DDT used in agriculture (1960–72) are not known, the available figures need not be extrapolated as they are about correct with minor variations.

(4) It is usual for genetic mutations for insecticide resistance to be less "fit", and reversion towards susceptibility generally occurs in the absence of insecticidal pressure. This was observed in *A. culicifacies* after withdrawal of spraying or change of insecticides in Maharashtra state in 12 units (28 villages)[4].

(5) Irrigation schemes contributed to the proliferation of the existing mosquito population which had become resistant in large parts of the country. It is incorrect to assume that the process of selection started *de novo* in the newly irrigated fields.

(6) In certain areas, a certain degree of contribution of the use of insecticide in agriculture in accelerating the pace of resistance in vectors of public health importance is understandable, and examples can be found to support this view. But it is difficult to believe that the massive quantities of insecticides used in public health and directed towards the malaria vectors were not the primary cause of widespread insecticide resistance.

The doubts raised by Chapin and Wasserstrom about the value of high-yielding crop varieties are a serious matter for a developing world striving hard to increase food production by introducing such varieties. The singling out of these crops as the main culprits for the resurgence of malaria without any authentic data is unjustified, and has been rightly condemned by Bruce-Chwatt as a "garbled account"[6].

Muscling in

Sir — It is very misleading for muscle biophysicists to continue to refer to the anterior byssal retractor muscle (ABRM) of *Mytilus* as an example of unstriated (=smooth) muscle (*Nature* 299, 308; 1980). For almost 30 years, since the ABRM was first examined by electron microscopy, it has been realized that this muscle in fact enjoys a very regular, striated, ultrastructure. There is a highly orderly arrangement of thin and thick filaments, although they are arranged obliquely rather than transversely, in the relaxed muscle. The correct designation for this type of muscle is *obliquely-striated.*

NEWS AND VIEWS

More speculation about oncogenes

Last week's reports of the surprisingly simple difference between a normal human gene and its equivalent in a human cancer cell is not merely important but provoking. What will happen next?

What follows is pure speculation. Those of an austere temperament should turn the page. Others, especially armchair molecular biologists, may welcome an opportunity to compare their private musings with the public hostages to fortune below. But in reality, nobody needs to be ashamed, for the discoveries described last week lead directly to a paradox.

The discoveries[1,2] are concerned with the difference between a normal human gene responsible for the production of a protein called p21 and the corresponding gene in cells derived from a bladder carcinoma; the difference consists of the replacement of one nucleotide by another precisely thirty-five units from the point in the functional gene at which the transcription of DNA into RNA begins. So the presence of the abnormal gene is a sign that cells derived from the bladder cancer have the properties of cancer cells, but not of course a proof that this simple mutation caused the malignancy in the first place. (This does not diminish the importance of the discovery, whose immediate interest is that it points directly to the protein p21 as one whose inknown function must play a crucial role in the biochemical functioning of both normal and malignant cells.) But it is also known that the mouse cells used as touchstones of carcinogenesis, peculiar though they may be, are also made cancerous ("transformed") when they are dosed with the normal gene for p21 provided that it is suitably equipped with the nucleotide sequences known to be necessary for viral replication in a vertebrate cell. The paradox is merely the question why the production of a small amount of an abnormal protein should have physiological consequences very similar to those of the production of an abnormally large amount of the normal protein.

Paradox

A paradox is a conflict between the conclusions of two apparently logical arguments. Paradoxes are usually resolved by the discovery that one argument or the other contains a hidden flaw, often of a semantic character. Can the Weinberg-Barbacid paradox be as easily resolved? That could be most simply accomplished if a little of the abnormal version of p21 and a lot of the normal protein were not different from each other but identical, at least in respect of the cancerous properties of the transformed cells. But how could that be? Both groups reporting last week point out that the effect of the genetic mutation they have found is that the simple amino acid glycine at position twelve in normal p21 is replaced by valine in the abnormal version, from which they infer that the altered protein molecules are less likely than normally occuring p21 to begin (from the end carrying a free amino-group) with a tidy coil of roughly helical structure.

This comparison connot however be exact. Even the tidiest helical protein structure is not helical forever. It must be supposed that from time to time the helical ends of normal p21 will be unwound, or that there will be some temperature-dependent proportion of normal p21 molecules that have the configuration now inferred for the abnormal variety. So is it possible that the similarity of the effects of small amounts of abnormal protein and large amounts of the normal variety, at least in respect of their cancerous properies, arises because large amounts of the normal protein provide small (but "sufficiently large") amounts of the abnormal configuration? That would be a semantic resolution of the paradox.

This speculation (it is not an argument) then raises the intriguing possibility that normal p21 in normal cells has two distinct functions, one involving the more common tidy helical structure of the first score or so of amino acids, the other requiring a structure similar to that inferred for the abnormal protein. So far, so good, but even speculation now abruptly stops. The normal function of normal p21 is entirely obscure, so that it is profitless to go guessing at the abnormal function. Fortunately, real molecular biologists will not be at a loss. Indeed, one of the obvious lines of enquiry now suggested is to use the techniques of genetic manipulation to right the changes on the first dozen or so amino acids of p21 to discover which parts of the structure are essential for the transforming activity of the abnormal gene. Telling how that part of the molecule functions will require more luck.

Evolution

This line of speculation leads to another. If the presence of an abnormal gene for p21 in a human bladder cell can have such profound effects, and if the frequency of radom mutations is as great as often supposed, by what means in the evolution of vertebrates has it been arranged that these lethal mutations are selectively suppressed? The question is more taxing than that of understanding the conservation of other genes that have survived long stretches of evolution more or less unchanged, for then it is at least possible to suppose that a cell inheriting an unwanted mutation will simply die unnoticed. But if taken at its face value, a mutation at position 35 of the p21 gene (or presumably at the preceeding one as well) will transform the cell which carries it into a form that grows successfully, and which proliferates. So it is natural to postulate some biochemical mechanism for removing these lethal mutations before than can do much damage.

This, of course, is not a novel speculation. Armchair oncologists were onto it while molecular biology was in its infancy. But two plausible conclusions follow. First, if the difference between a normal and a cancer cell is as delicate as now appears, the case for an active molecular mechanism for removing unwated mutations is strenthened (which is not to suggest that it is within sight of being understood). And second, given such a mechanism, the occurence of the abnormal gene in cells taken from a human bladder cancer is much more likely to be the repository of the mechanism of cancer than its first cause. That is just as well, for it would otherwise be hard to account for the long induction period associated with most forms of cancer, as everybody has pointed out.

The snag, with speculation in this or any other fields, is that it cannot solve puzzles but only replace one puzzle by another. The discoveries reported last week by the Weinberg and Barbacid groups, are themselves based on a new technology patiently developed over the past decade, and on a mass of painfully acquired and still poorly-assimilated information about the behaviour of retroviruses (which carry genetic information as RNA, but which can integrate as DNA among the genes of the cells that they infect). They are sensational because they are so unexpected and because they have been made at the bench, not in the armchair. That is also how the next surprises will arise in this now exciting chase. They will not be long delayed.

Natural killers to rescue immune surveillance?

from Barry R. Bloom

Despite the myriad difficulties in finding definitive experimental verification, the idea of immunological surveillance holds a unique appeal for cellular immunologists. The existence of a surveillance mechanism for the continuous and systematic rejection of altered body cells was first inferred when it was found that specific cytotoxic T lymphocytes (CTLs)[1] could lyse allogeneic (non-self) cells and syngeneic (self) virus-infected or tumour cells. Soon apparent, however, was the disconcerting fact that athymic nude mice, which lack this mechanism, had no greater incidence of primary spontaneous, virally or chemically induced neoplasia than normal mice. It is in this context that the discovery of natural killer (NK) cells — present in both athymic and normal mice — renewed hopes that immunological surveillance might be a real phenomenon.

Natural killer cells represent an apparently heterogeneous population of cells with the capability of spontaneously lysing a variety of transformed cells, virus-infected cells and embryonal cells *in vitro*, without evident prior exposure to specific antigen *in vivo*. The revelation that NK activity is regulated by interferons, and also by interleukin (IL)-2, markedly heightened interest in these cells, if not their credibility.

Despite the extraordinary amount of information generated about NK cells in a very short period of time, recently reviewed at an excellent workshop* on natural killing, the most fundamental questions — the provenance and lineage of NK cells, their mode of recognition and their function *in vivo* — remain problematic.

The dogma implicit in much of cellular immunology, 'By their markers, shall they be known', is currently being confounded by NK cells. A large number of surface determinants have been identified on NK cells and have helped to establish their heterogeneity and define subsets, but most, if not all, of the markers are found on other cell types as well. In the mouse, NK cells, although lacking the Lyt 1 and Lyt 2 markers of helper and suppressor/cytotoxic T subsets, do share Thy 1, Qa4 and -5, Ly5 and asialo-GM$_1$ with T cells. Human NK cells express the OKT3, OKT6, OKT11 and to a lesser extent the OKT4 and OKT8 markers associated with immature and differentiated T cells. However, they also express the OKM1 marker found on monocytes and granulocytes. Murine NK cells express, in addition to Fc receptors for IgG, high-affinity IgE receptors, similar to mast cells and basophils. Worse yet, in short-term culture, the expression of markers can vary qualitatively from day to day[1]. Even the most useful and specific monoclonal antibodies (anti-NK1.1 in the mouse and HNK-1 [Leu/] in man) react with a greater proportion of cells than can be accounted for by NK activity. The recent observation (Stutman, Sloan-Kettering Institute) that one NK cell subset, termed NC cells, known not to be affected by interferon, is regulated by IL-3 which is also a mast cell growth factor, raises the possibility that specific growth factors may ultimately be helpful in resolving questions of NK cell lineage.

One of the controversies that has smouldered over the years is the relationship between NK cells and K cells, the latter being defined as cells possessing Fc receptors for IgG that have the ability to lyse antibody-coated target cells *in vitro*. These cells express almost all known NK markers yet clearly have a different mode of recognition and killing of target cells. Using the single-cell cytotoxicity assay, individual cells were shown to kill both NK-susceptible and antibody-coated targets, demonstrating that the same cell could carry out both activities[2]. Only in the germ-free piglet does that dichotomy remain (Kim, Sloan-Kettering Institute).

The selectivity or specificity of NK cells for certain target cells remains enigmatic. Many cloned NK lines have the ability to kill a wide variety of targets, including some not recognized by primary NK cells, yet some human clones have quite remarkable selectivity for only certain targets. It is unclear why some tumour or virus-infected cells are not lysed, and why some embryonal and normal cells are either killed or are capable of blocking killing of appropriate NK targets. Wigzell (Karolinska Institute) reported the intriguing finding of NK-like activity in two of six rat tumour-specific CTL lines. The cells had classical MHC (major histocompatibility complex) -restricted killing of the specific syngeneic chemically induced tumour target, but in addition could lyse xenogeneic NK targets (targets from a different species). An anti-idiotypic antibody was obtained which blocked the MHC-restricted tumour-specific killing, but did not affect the killing of the NK targets. This clearly indicated that recognition of the tumour-specific antigen and NK target structures are independent, and that receptors for NK targets are distinct from those for MHC-restricted specific antigens. It will be of interest to know whether exposure of these cells to the NK targets will clonally expand them for tumour-specific killing. Recently, human NK-like clones derived from mixed lymphocyte culture were found to have clonally distributed receptors distinct from MHC recognition[3]. These and most other experiments on NK cell recognition raise the question of whether there is a clonally distributed diversity of NK receptors for various target cells, or whether there is a class of surface structures common to some tumour cells, virus-infected cells and embryonal cells recognized by most NK cells.

If the mode of NK cell recognition remains mysterious, the mechanism by which they kill their targets is being solved, to the extent that they have become the paradigm for understanding cell-mediated cytotoxic mechanisms. Human and rat, but to a much lesser degree mouse, NK cells appear as large granular lymphocytes (LGLs), morphologically quite distinct from other lymphoid cells. A wide variety of studies ranging from microcinematography to the use of selective metabolic inhibitors indicate that lysis is mediated by vesicular secretion. Thus drugs that block vesicular secretion in other cell types, for example, mast cells, inhibit NK cell killing[4,5]; agents that degranulate, such as Sr^{2+}, both deplete the granules from LGLs and inhibit killing[6]. The stimulus–secretion model, initially suggested for NK cells by Roder, would hold that the critical requirements for killing are (1) binding to target cells, (2) movement of the uropod containing the granules into apposition to the target[7], (3) Ca^{2+}-dependent degranulation or release of an NK cytotoxic molecule, (4) binding of the cytotoxic factor to the target and (5) lysis of the target by the released factor. An NK cytotoxic factor has been found to be released from mouse NK cells and human LGLs on interaction with NK-susceptible targets[8,9], which has the ability to lyse NK-susceptible as well as some resistant targets. Target cells can be resistant to NK killing if they either fail to bind NK cells, or fail to bind or succumb to the cytotoxic factor. Because several laboratories failed to find production of oxygen radicals or inhibition of NK killing with radical scavengers, a proposed role for oxygen metabolites in mediating NK killing[10] has been met with some scepticism. If there are independent receptors for binding of NK cells and an NK cytotoxic factor, these mechanistic studies can explain some of the apparent selectivity for killing various target cells. From these studies, one hopes it will also be possible to define the nature of the NK cell defects found in several disease states.

To achieve credibility NK cells must be shown to perform some important functions *in vivo*. Many years ago, the late Gustavo Cudkovicz and collaborators[11] found a genetic association between NK activity and the acute rejection of allo-

Barry R. Bloom is Professor and Chairman of the Department of Microbiology and Immunology, Albert Einstein College of Medicine, Bronx, NY 10461.

*'Workshop on Natural Killing' held at Quail Roost, North Carolina on 31 August–3 September 1982 was organized by H S Koren and R B Herbermann

0028-0836/82/460214-02$01 00

geneic bone marrow grafts. The antigen that was recognized in this system was found to be closely linked to the *H-2D* locus. Studies on this haematopoietic histocompatibility locus gave rise to the notion that NK cells may be important not only for acute rejection of bone marrow and other grafts, but also for maintaining regulation or surveillance of the bone marrow itself.

Genetically NK cell-deficient *beige* mice as well as mice selectively depleted of NK cell function by treatment with antibodies to NK1.1 antigen, asialo-GM1, or mouse interferon are found to have increased metastases of a variety of transplanted tumour cells, suggesting that NK cells have a role in restricting metastases. It has been very difficult to show, however, even in *beige* mice, that NK cells have a significant role in restricting spontaneous viral or chemical tumorigenesis. One difficulty in these studies is that almost all chemical and viral carcinogens profoundly depress NK cell function, often for very long periods of time. In a recent issue of *Nature* (4 November, p.31), Warner and Dennert provide compelling evidence that NK cells can mediate three major surveillance functions *in vivo* — rejection of bone marrow grafts, restriction of tumour metastases and inhibition of primary tumorigenesis. Dennert was the first to report continuous cloned cell lines with NK-like activity, and the ability of cloned NK lines to mediate these three surveillance functions *in vivo* suggests that the power of cloned cell lines will be no less great in providing a unique tool for studying mechanisms and functions of NK cells than it has been in the case of B and T cells. While questions remain whether the effects are mediated directly or indirectly by the cloned cell lines, and what the appropriate growth factors are that maintain the cells in an active state *in vivo*, these experiments provide direct evidence that NK cells can exert a profound regulatory role in acute graft rejection and in restriction of neoplasia and metastases. They provide an important model for exploring the role of NK cells in controlling viral, bacterial and parasitic infections *in vivo*. They will also be cited to justify the possibility of ultimately (in immunology, that means within two years) intervening therapeutically in human disease using purified LGLs or cloned NK cells. □

Call *Alvin* for hot science

from Roger N. Anderson

RECENT discoveries of deep-ocean hydrothermal vents in the Mariana Trough back-arc basin have stirred new excitement within the geological and biological communities. In the past few years, hot springs billowing forth metal-laden waters at temperatures up to 350°C have been found all along the East Pacific Rise crest from 21°N to 12°N and 20°S. Fantastic and unique biological communities live near these hot springs, ingesting sulphur-eating bacteria. But to date, all these organisms and associated 'black-smokers' have been found in the eastern Pacific close to a mid-ocean ridge. Now a new hot-spring vent area has been found — not only is it in the western Pacific but it is also above a subduction zone, where the Pacific Plate is being forced under the Philippine Plate. Both the biological and geological settings are in distinct contrast to the eastern Pacific hot vents. Scientists are clamouring to document similarities and differences between the mid-ocean ridge hot vents and the back-arc basin vents.

But first the evidence. As with the previous hot spring discoveries[3,4], oceanic heat flow measurements were the first to suggest hot-vent activity in the Mariana Trough[5]. Very hot patches of sea floor emitting more than two watts of geothermal power per metre (50 times normal) and bizarre temperature-depth recordings were strong hints of hot spring activity. A deeply towed acoustic imager with supporting temperature sensor next identified hot water[6] (admittedly only 0.1°C hotter than surrounding ambient seawater) associated with volcanic activity at the crest of the back-arc basin 'rift valley.' Metal deposits usually associated with massive generation of sulphide ore at sea-floor hot springs were also dredged. Now, Yoshio Horibe of the Ocean Research Institute, University of Tokyo, and Kyung-Ryul Kim and Harmon Craig of the Scripps Institution of Oceanography have uncovered conclusive evidence for the existence of hot vents in the Mariana Trough[7].

Hot vents carry rare gases from the magma below the sea floor to the ocean column. Thus if samples from the water column above suspected vent sites[3] are analysed, helium, hydrogen and methane anomalies can be found. This technique successfully searched out hot springs at 20°S on the East Pacific Rise.

Aboard the research vessel *Hakuho-maru* of the University of Tokyo, samples *m* from the back-arc basin spreading centre and from the waters above the two-watt power source were analysed for methane in February 1982. Methane is a clear product of hydrothermal vents in the eastern Pacific, but is consumed so quickly by bacteria floating in the ocean that a methane anomaly requires an active vent to spew hot hydrothermal waters into the ocean.

First, the scientists went to the two-watt area but no methane anomaly was found — the heat must be a remnant of a now-dead vent. Then at the back-arc basin spreading centre, the largest methane anomaly ever found in the oceans was recorded (see the figure). Later shore-based analysis verified this finding by showing a staggering 26 per cent increase in primordial ^{3}He. Hot vents must be active at the crest of the Mariana Trough back-arc basin.

Why the excitement? Vents are likely to exist all up and down the East Pacific Rise crest. Consider the biology. Will any living creatures be found? If so, will they be similar to those in the eastern Pacific: the large eastern Pacific clams are a form of mollusc indigenous to the northeastern coast of North America. Will the Mariana Trough have 'Japanese' clams? Will the spectacularly coloured tube-worms be

0028-0836/82/460215-02$01 00

present? Jack Corliss of Oregon State University has even postulated that life on Earth originated at 'black-smokers'!

Now to the geology: the subduction zone clearly supplies volatiles (for example, water to the volcanoes of the island arcs). Does the addition of this volatile source to the back-arc basin spreading centre change the chemical composition of the hot springs? And if so, does it change the metallogenesis occurring at spreading centres versus that at back-arc basins? These hot vents produce a significant quantity (about 20 per cent) of the mined metals in the world. Here is a chance to see the formation of metals in action today.

What next? Now it is time for the diving submarine *Alvin* to sample these Mariana Trough hot vents. Plans are being formulated for a diving season in winter–spring 1984–1985 in the western Pacific. Those of you who might have unique science to offer to the exploration of the Mariana Trough hot vents should contact the *Alvin* Review Committee, University National Ocean Laboratories (UNOLS) Office, Department of Oceanography, University of Washington, Seattle. □

Gene conversion between repeated genes

from Thomas Petes and Gerald R. Fink

In the now 'classical' studies of gene conversion, the conversion of one gene to another occurs only among allelic genes present in single copies on homologous chromosomes. Recent work indicates, however, that among repeated genes, conversion can occur even when the genes are located on non-homologous chromosomes. In this article, we will discuss both examples of gene conversion and also the recent suggestion from Egel[1] and Baltimore[2] that gene conversion events occur not only in fungi but also in the cells of higher mammals. We consider that gene conversion in fungi and recombination events in mammalian cells might well be different.

Fungi are particularly suited to the study of gene conversion because all the progeny from a single fungal meiosis are sequestered in a structure called the ascus. For a heterozygous pair of alleles *A* (wild type) and *a* (mutant), the expected pattern of meiotic segregation is *2A* segregants and *2a* segregants. Gene conversion is detected by deviations of the type *3A:1a* or *1A:3a*. In tetrads with *1A:3a* segregation, Roman[3] showed that all three mutant alleles were identical. Thus gene conversion represents non-reciprocal precise transfer of information between two genes, either from *A* to *a* or from *a* to *A*. Extensive genetic analysis of this process has resulted in several other generalizations. For all loci, conversion can occur either from mutant to wild type or wild type to mutant. In *Saccharomyces cerevisiae*, conversion is often equally frequent in both directions, although significant deviations in one direction have been seen[4] Meitoic gene conversion in *S. cerevisiae* occurs but at a frequency of about one per cent per locus. Mitotic gene conversion also occurs but at a much lower frequency (10^{-4} - 10^{-6}). Deletions and insertions are converted at frequencies comparable with those found for point mutations[5]. For all organisms where genetic analysis has been possible conversion is non-randomly associated with reciprocal recombination[6].

Holliday[7] suggested that gene conversion is the result of heteroduplex formation between allelic genes, followed by mismatch repair. Mismatch repair involves the excision of one strand of the heteroduplex followed by resynthesis using the unexcised complementary strand as a template. This mechanism allows the faithful transfer of information from one gene to another. Holliday and others[8] have proposed that heteroduplex formation, which creates a potential site for gene conversion, is an obligatory intermediate in the process of reciprocal recombination.

Recombination events between single-copy genes are restricted to events between equivalent sites on homologous chromosomes, but repeated genes on nonhomologous chromosomes should also be capable of recombinational interactions. Using recombinant DNA procedures and the yeast transformation techniques, Scherer and Davis[9] constructed haploid *S. cerevisiae* strains with two copies of the *his3* gene (each copy containing a different small deletion); the genes were located on nonhomologous chromosomes. Since the wild-type *his3* gene was formed without concomitant formation of the double mutant, they concluded that His$^+$ recombinants were generated by gene conversion. Similar procedures were used to show that mitotic gene conversion occurs between repeated genes on the same chromosome[10]. Gene conversion has also been seen between naturally occurring repeated yeast genes. Ernst *et al.*[11] showed that some revertants of iso-1-cytochrome *c* mutations were the result of gene conversion between the partially homologous iso-1- and iso-2-cytochrome *c* genes. All these examples of gene conversion between repeated genes in *S. cerevisiae* are mitotic events but meiotic intrachromosomal gene conversion has also been demonstrated[11].

Meiotic gene conversion between repeated tRNA genes in the fission yeast *Schizosaccharomyces pombe* is reported by Munz and his colleagues in this issue of *Nature* (p.225). They show that an inactive UGA-reading serine tRNA suppressor gene (the suppressing activity lost because of a secondary mutation in the tRNA gene) can be re-activated by a recombination event. Assuming that all the secondary inactivating mutations used in the study do not have an extremely high rate of reversion, Munz *et al.* suggest that the inactivating mutations are removed by conversional interactions with other serine tRNA genes in the genome — one of these is on the same chromosome as the serine suppressor tRNA, the other is on a different chromosome. In support of these conclusions, they show by Southern blot analysis and DNA sequencing that serine tRNA genes can be altered in a single genetic event at multiple positions within the gene. Such alterations are much more easily explained as gene conversion events than as mutations. Remarkably, there is less than 200 base pairs of homology between the interacting tRNA genes which undergo this conversion event.

Gene conversion events between repeated genes, such as those described above, are likely to have two important genetic consequences. First, continued cycles of gene conversion within a family of repeated genes could lead to the maintenance of sequence homogeneity within that family[14]. Second, gene conversion can produce sequence diversity since conversion between repeats that differ at more than one position can form new combinations of sequences[1,2,9-12]. The net effect of conversion is likely to be a complicated function of the rate of conversion relative to mutation, the location of the interacting repeats, the length of the repeats and other factors.

Since gene conversion between repeated genes is likely to have important genetic consequences, it is obviously of interest to determine whether this type of conversion occurs in higher cells. Slightom *et al.*[15]

Thomas Petes is in the Department of Microbiology, University of Chicago, 920 East 58th Street, Chicago, Illinois 60637, and Gerald R. Fink is in the Department of Biology, Massachusetts Institute of Technology and Whitehead Institute for Biomedical Research, Cambridge, Massachusetts 02139.

found that the duplicated human γ^A and γ^G genes within a single chromosome were more similar than two allelic γ^A genes. They proposed that intrachromosomal gene conversion was the most economical explanation of the data. Similar observations have also been made recently for several other classes of repeated genes in higher organisms[1,2,16].

We believe that gene conversion may explain some recombination events between repeated genes in mammalian cells, but the process is yet to be demonstrated experimentally and may be different from that found in fungi. The observations in higher eukaryotes can be explained by unequal double cross-overs as well as by conversion. So far, no one has developed a system in higher organisms that allows examination of both participants in the recombination event before and after the postulated conversion. In considering gene conversion as a mechanism that maintains homogeneity among repeated genes[14], it is important to remember that conversion in fungal systems is often associated with reciprocal recombination[6]. It is not clear, therefore, how frequent cycles of gene conversion would be dissociated from the production of chromosomal deletions, inversions and translocations. This problem should be particularly acute in mammalian genomes where repeated sequences constitute a large fraction of the DNA. It is possible that in mammalian cells gene conversion is not obligatorily associated with reciprocal recombination. Even in fungi there is a class of mitotic gene conversions that are not associated with reciprocal recombination[10,17,18]. Over the next few years, it is likely that a combination of recombinant DNA techniques and DNA-mediated transformation will help to determine whether the recombination events observed in mammalian cells have all the properties of gene conversion events in fungi. □

The origin of tektites — settled at last?

from Peter J. Smith

TEKTITES, those small glassy objects limited to a few well-defined regions of the Earth's surface, have haunted geologists for more than a century. Like country house ghosts, they have never been part of the investigative mainstream but have given rise to a variety of weird and wonderful explanations that attract the occasional attention of the wider community particularly when it has seemed that a new technique might throw some light on their nature and origin. Unlike country house ghosts, on the other hand, they are undoubtedly real, having been regarded as fine ornamental material since at least the time of Cro-Magnon man, about 31,000 years ago.

It was perhaps unfortunate that early scientific attention should have been directed towards Czechoslovakian tektites (moldavites) from a region of ancient European glassmaking. The result, during the nineteenth and early twentieth centuries, was a long time-wasting debate over whether tektites are real or artificial, productive only in the sense that the right conclusion was reached in the end. By then, however, it had already become clear that if tektites were natural they were not to be easily explained, for there was no obvious source, or 'mother lode'. The way was thus open to a wide range of possible explanations from the down-to-earth (literally and figuratively) to the bizarre.

Terrestrial volcanism was the obvious first choice; but it soon became evident that there were significant chemical differences between tektites and obsidian, the more common glassy material of undisputedly volcanic origin. Besides, candidate volcanoes close to the tektite zones, or 'strewnfields', were hard to find. To avoid some of these difficulties, Dunn (*Victoria, Geol. Surv. Bull.* **27**, 3; 1912) proposed an elaborate derivation of tektites from obsidian, involving lightning strikes in a very dusty atmosphere packed with hot gases, but it was not sufficient to overcome the objection that tektite compositions were far removed from those of terrestrial volcanics generally. During subsequent decades, tektites were to be attributed to, among other things, the heating of stony meteorites, the collision between a meteorite and a natural Earth satellite, the drying-out of siliceous gels acted upon by humic acid, and the fall of antimatter, although neither these nor many other hypotheses stood the test of time, if they ever stood at all.

What we are left with in 1982 are just two contending hypotheses, both of which involve extraterrestrial bodies. According to one, tektites are volcanic products ejected from the Moon; and according to the other, they are fragments ejected from the Earth itself by cometary or meteoritic impact. As work on returned lunar samples has proceeded, a lunar volcanic origin of tektites has come to seem less and less likely, although there are those, most notably O'Keefe (*Geochim. cosmochim. Acta* **44**, 2151; 1981), who would strongly dispute that view. The alternative explanation, by contrast, has risen in popularity, bolstered no doubt by a natural desire to avoid exotic solutions wherever possible. The hot money these days is on the idea that tektites result from the impact melting of terrestrial rocks, expecially sediments; and the odds in favour of that must surely have risen with the publication by Shaw and Wasserburg (*Earth planet. Sci. Lett.* **60**, 155; 1982) of a detailed study of the world's tektites using Sm–Nd and Rb–Sr systematics.

There are four tektite strewnfields, within each of which the tektites have the same K–Ar and fission track ages. Thus the North American, European, Ivory Coast and Australasian tektites are about 35, 14, 1.3 and 0.7 million years old respectively. These ages represent the times at which the tektites were last molten; they say little about the types of rock from which the tektites were formed, how they formed, or whence they came. Fortunately, however, it is now possible to determine rather more, both comparatively and absolutely, about the provenance and evolution of rocks from the behaviour of the Sm–Nd and Rb–Sr decay systems.

As for the comparative, one way of expressing isotopic ratios is to use the ε notation. Thus ε^{Nd} (0) is the measured deviation (in parts in 10^4) of the $^{143}Nd/^{144}Nd$ ratio from the present-day chondritic value of 0.511847; and ε^{Sr} (0) is the deviation (also in parts in 10^4) of the $^{87}Sr/^{86}Sr$ ratio from a model undifferentiated mantle reservoir value of 0.7045. The point about ε values is simply that they are different for different rock types. Shaw and Wasserburg have measured ε values for geographically and geochemically representative samples from all four tektite strewnfields and find that ε^{Nd} (0) is always negative and ε^{Sr} (0) is always positive and large. These values are characteristic of old terrestrial continental crust. They exclude continental material which has been derived from the mantle very recently, for that has ε values close to zero; and they exclude oceanic crust, because that has positive ε^{Nd} (0) values and negative ε^{Sr} (0) values. The isotopic data thus match the chemical data, for, as many

Peter J. Smith is editor of Open Earth *and reader in the Department of Earth Sciences at the Open University, Milton Keynes MK7 6AA.*

0028-0836/82/460217-02$01 00

workers have pointed out since at least 1917, the chemistry of tektites resembles nothing so much as continental sediments, especially sandstones. There are no known lunar rocks having major and trace element compositions similar to those of tektites, and there are no known meteorites with these compositions.

The second important discovery made by Shaw and Wasserburg is that within each tektite group ε^{Nd} (0) is uniform whereas ε^{Sr} (0) is highly variable. This reflects what earth scientists already suppose about the different types of information provided by the Sm–Nd and Rb–Sr systems. Assuming that concentrations are high enough to measure, any radioactive decay system will give an age for the rock concerned, but the term 'age' needs careful interpretation. The major fractionation of Sm and Nd appears to occur during the partial melting of mantle material to produce crust, and the Sm–Nd system is relatively undisturbed by such processes as weathering and sedimentation. Moreover, Sm and Nd are refractory and thus not readily fractionated by differential volatilization on impact melting. The Sm–Nd age of a tektite should therefore represent the time of formation of the crustal material from which the tektite was ultimately derived, and uniformity of ε^{Nd} (0) within a single tektite group inspires confidence that the Sm–Nd system is dating precisely that event. The Rb–Sr system, by contrast, can be severely disturbed by sedimentation, volatilization, weathering and diagenesis. It is only to be expected, therefore, that a tektite group will provide a range of ε^{Sr} (0) values and Rb–Sr ages reflecting the varied history of the tektite source rocks and descending to the last major parent–daughter fractionation event. In short, if nature is behaving itself, all tektites within a group should have a common Sm–Nd age, a range of younger Rb–Sr ages and, of course, a common and even younger K–Ar age representing the time at which the tektite themselves formed.

And thus it turns out. The Sm–Nd ages obtained by Shaw and Wasserburg for the North American, European, Ivory Coast and Australasian tektites are, respectively, about 650, 900, 1,900 and 1,150 million years. In other words, all the ages are consistent with the tektites' having been formed from Precambrian crust. The Rb–Sr data then indicate what happened between the formation of that crust and its conversion to tektite. The European tektites, for example, were derived from sediments laid down only about 20 million years ago. Interestingly, sediments in the nearby Ries Crater have ε values and isotopic compositions similar to those of the tektites themselves. Moreover, the age of the oldest basement in the crater area agrees well with the Sm–Nd age of the tektites. The new data thus support an earlier suggestion that the Ries Crater was formed by the impacting body that also gave rise to the tektites.

WHILE watching the grand display of aurora on Friday night from our roof, at about 6h. 7m., my wife and I saw a strange gleam of light rising above a bank of cloud on the eastern horizon, nearly vertically below the Pleiades, like the gleam of another moon rising in a haze. It grew out slowly, as we watched it, into a strong beam of white light slanting towards the south, and we stood in wonderment as it lengthend out making straight towards the moon. Presently its tail was dis-engaged from the cloud, and it stole through the sky like a long luminous nebulous "cigar ship" exactly across the moon, and away down into the west, sinking as slowly as it had risen. You will probably receive many accounts of this strange apparition. It will be interesting to know the position relative to the moon in which it was seen by different observers. Was it clear of the earth's atmosphere or not?

HUBERT AIRY
Woodbridge, November 19, 1882.

The Ivory Coast strewnfield has also been associated with an impact structure, namely, the Bosumtwi Crater. The rocks around this crater have ages comparable with the Sm–Nd age of the tektites. The Rb–Sr systematics indicate that the tektites were formed from Precambrian sediments about 950 million years old, although the sediments have not been identified yet. The North American tektites, by contrast, have no known source crater. Moreover, the fact that the material that went to form the tektites was derived from the mantle as recently as the late Precambrian rules out most of the North American Precambrian shield, and the sediments derived therefrom, as a source region. Similar age criteria refute the recent suggestion from Dietz (*Meteoritics* **12,** 145; 1977) that the Popigai astrobleme of Siberia is the source of the North American strewnfield. The only known continental material of the required age is the late Precambrian crust constituting the east-southeast margin of the Appalachian orogenic belt, although no suitable crater has been identified within it.

Little more can be said about the origin of the North American tektites, except that the immediate source material was sedimentary, for the Rb–Sr proved unsuitable for the determination of an age of sedimentation. Not the least interesting conclusion to be drawn from the work of Shaw and Wasserburg, however, is that an oceanic impact for the origin of tektites is not ruled out by the restriction that tektite source material cannot be oceanic crust. Although the effects of the impact at the Ries Crater extend to depths of about 2 km, the tektites supposedly produced by the impact were formed from sediments which appear to have been only a few tens of metres thick at the time. The implication of this is that an oceanic impact could well generate tektites simply by sampling thin continentally derived sediments lying on top of the basaltic oceanic crust. In other words, an impact origin of tektitites is not precluded by failure to discover a suitable impact structure on land.

In the case of the Australasian strewnfield there are several candidate craters on land — the Zhamanshin and Elgygytgyn Craters of the USSR and an unnamed crater-like structure in Cambodia. Nothing much is know of the Cambodian crater and the Elgygytgyn Crater can be ruled out on age grounds. The most touted possibility is the Zhamanshin Crater, but the case for it is weak, if not nonexistent. For example, this crater is associated with tektite-like objects known as irghizites, which have chemical compositions similar to, but Nd isotopic compositions quite different from, those of the tektites of the Australasian strewnfield. It is possible in principle that both the irghzites and the Australasian tektites were produced at the same crater but that the irghizites managed to take up a proportion of the impacting meteoritic material, although Shaw and Waserburg show that it is impossible in practice to obtain the correct ε values for the irghizites simply by adding chondritic material to the tektitic. It seems much more likely that the impact body that supposedly gave rise to the Australasian tektites fell in the ocean; but wherever it struck, it generated tektites from continentally derived sediment about 250 million years old.

What is impressive about the story pieced together by Shaw and Wasserburg is its overall coherence and internal consistency. So can we take it that the tektite issue is now settled? Or will the lunar volcanologists fight back, as they have so often done before, with a quite different interpretation of the same data? We shall see. In the meantime, it could well be objected that, coherent or not, the cometary impact hypothesis is no less exotic a mechanism for the production of tektites than is lunar volcanism. But somehow it does seem less so these days. Recent calculations on the frequency with which comets large and small might be expected to reach the Earth's surface, and the remarkably cool way in which the earth science community has been willing to consider seriously the suggestion by Alvarez *et al.* (*Science* **208,** 1095; 1980) that cometary impact may have been responsible for the Cretaceous–Tertiary extinctions, suggest that the rigid anti-catastrophism characteristic of geological thinking since the time of Hutton and Lyell is now dead.

Yet at least one puzzle remains, and remains unremarked. If cometary impacts have been responsible for biological extinctions throughout the Phanerozoic, why have they apparently only generated tektites during the past 35 million years? Curious. □

Learning, forgetting and the cell biology of memory

from Miranda Robertson

PERHAPS memory has proved such an intractable problem for so long because, like embryogenesis — the other central metazoan mystery — it is a property of interacting cell systems, depending on cellular signals whose mechanisms seem likely to be the last to yield to molecular analysis. Charles Stevens (Yale University), closing a recent meeting* primarily concerned with the biology of memory (but see box overleaf), argued that memory and development are not merely similar problems but one and the same. From this point of view, the traditional distinction between 'hard-wired' and plastic neuronal systems is reduced to a matter of timing: the final differentiation of some of the neurones in a plastic system is delayed until long after maturity.

Stevens's near-impossible brief was an overall synthesis of a conference that began with the properties of learning and forgetting in damaged and undamaged vertebrates and descended fairly precipitously to the properties of ionic channels in lower forms of life. Paul Rozin (University of Pennsylvania), discussing the adaptive properties of learning at the upper end of this spectrum, gave some arresting examples of plastic systems with a hard-wired basis. The most obvious of these is the imprinting of precocial birds, which follow and later make sexual advances to anything that looks like the first moving object they see (usually their mother); the responses in this case are hard-wired, only the stimulus being determined by experience. More subtle constraints may operate in mammalian learning: for example, a rat taught to associate a light and a specific taste with malaise will learn to avoid the taste, not the light.

One hope of those engaged in research on the neuropsychology of memory is to identify specific brain structures essential for its consolidation. Given that memory can be regarded as a property of any neural circuit whose activity is modifiable by experience, this may seem an optimistic aim. It is therefore perhaps surprising that damage to the medial temporal lobes of the human brain should have proved to be specifically associated with failure of memory for events occurring after the injury, in the absence of sensory or cognitive deficits. In the light of recent analyses, however, the memory deficit begins to look less general than it might at first appear. Brenda Milner (McGill University), for example, summarized recent evidence for lateralization: lesions of the left medial temporal lobe generally lead to failure of verbal memory, lesions of the right to deficits in memory for spatial position.

A more profound specialization still has been suggested by the research of Neal Cohen in the laboratory of Larry Squire (University of California, San Diego). He has demonstrated that medial temporal lesions affect only what he calls declarative learning — or 'learning that'; damaged patients are still perfectly capable of procedural learning — or 'learning how'. Thus for example, a patient with almost complete failure of verbal memory can be taught to read mirror-reversed writing and retain the skill on testing three months later, though he will not remember having been taught it[1]. This is a particularly telling example because reading reversed print is a verbal skill. Squire believes that procedural learning may be different in kind from declarative learning: it takes longer to acquire and is much less easily forgotten, as well as being resistant to brain damage affecting other kinds of memory. Whether this really reflects a difference in kind, or is a function of the number of neural pathways involved, is impossible to say.

Without doubt the most striking and provocative data to be reported at the conference were those of Fernando Nottebohm (Rockefeller University) on song learning in canaries, which is another clear case of partial plasticity. The song of male canaries has an invariant species-specific basis that is elaborated by learning, and the songs of individual birds will change considerably from one year to the next. The ability of the birds to learn new songs (though not their ability to sing) depends on a specialized neural centre known as the hyperstriatum ventrale, pars caudale (HVc). The size of the HVc, and that of a lower song control centre, the nucleus robustus archistrialis (RA), is correlated with the size of the birds' song repertoire — being very small in females, which are songless, and increasing in males during the spring, when testosterone levels are high and the season's song repertoire is growing. In the RA these size differences can be accounted for in part by differences in the size of the dendritic trees of the neurones[2] and it seems likely that similar changes occur in the HVc.

But recent investigations have suggested the more startling possibility that in the HVc the size fluctuations may be partly due to the continual recruitment and loss of neurones in the nucleus. The evidence for such turnover comes from experiments on female canaries. Under the influence of testosterone, the female HVc doubles in size[3]. In the light of this dramatic increase, Nottebohm, with his colleague Steven Goldman, went on to investigate whether testosterone might be inducing cell proliferation and found that new HVc neurones were appearing all the time even in the absence of the hormone. They are accordingly now monitoring the HVcs of both male and female canaries at monthly intervals to see if they can detect changes in the rate of cell division; and Nottebohm suggests that the addition and loss of neurones in the HVc reflects a continuous 'updating of the software' of song production — cell turnover in females reflecting, perhaps, the complementary need to recognize each new season's repertoire of serenades.

The implication of such drastic changes is that learning entails an irreversible change in the HVc neurones so that new learning requires new cells containing uncommitted DNA. If this is the case, there is certainly a radical difference between avian and human song learning; but so little in known of the cellular basis of memory that the possibility cannot be dismissed.

It is generally assumed that learning entails short-term changes in the activity of groups of neurones, leading to longer-term or effectively permanent changes in synaptic resistance. Evidence from the effects of trauma (for example concussion or electroconvulsive shock) suggests that while the short-term changes may have a time course of minutes to hours, longer-term consolidation may continue for up to two years.

Both Eric Kandel (Columbia University) and William Quinn (Princeton University) addressed themselves to the possible molecular basis of these changes in animals with simple nervous systems. Kandel has focused on the modulation of the gill-withdrawal reflex in the sea-snail *Aplysia*. This can be elicited by touching the animal's siphon, and enhanced by simultaneous stimulation of its tail. Kandel has shown that such sensitization, which can be regarded as a simple form of learning, depends on presynaptic modulation by serotonin of the activity of the sensory neurones mediating the reflex. Serotonin binds to receptors on the presynaptic nerve terminal, activating adenylate cyclase and leading to the cyclic AMP-dependent phosphorylation of a potassium channel in the presynaptic membrane. The resultant closure of the potassium channel prolongs the action potential, thus increasing the influx of calcium and the release of transmitter onto the postsynaptic cell[4,5]. The same mechanism has more recently been shown to underlie a simple form of classical conditioning in which a weak stimulus to the tail precedes the stimulus to the siphon.

Quinn has sought, by the analysis of

learning mutants, to establish a similar kind of mechanism in *Drosophila.* One mutant, *dunce,* has a defective phosphodiesterase and thus presumably abnormal cyclic AMP metabolism[6]; a second, *rutabaga,* isolated by Patricia Szieber in his laboratory, has been shown by Margaret Livingstone to be deficient in adenylate cyclase activity. Quinn is now hoping to identify the neurotransmitter whose receptor is (presumably) coupled to the crucial adenylate cyclase, so as to explore further the possible parallel with *Aplysia.* Preliminary evidence implicates either dopamine or serotonin, which is particularly interesting in view of recent evidence that the distribution of dopamine is correlated in rat brain with that of a membrane protein whose phosphorylation can be shown *in vitro* to depend on the dopamine-activated synthesis of cyclic AMP[7].

Thus catecholamine-activated protein phosphorylation may be part of a general mechanism of memory. But how far can the phosphorylation of ionic channels explain the phenomenological properties of memory? Stevens, in his summary discussion, pointed out that it cannot on its own account for any memory lasting more than two or three weeks, which is the maximum lifetime of a membrane protein. If learning depends on the phosphorylation of membrane proteins, then neurones must be re-programmed to keep phosphorylating them. It was this kind of consideration that led him to suggest that memory can be seen as the last step in neural differentiation: a final change in gene expression that is reserved until after birth and is contingent on experience. Just as during development, a morphogenetic signal changes the state of differentiation of a cell and thus its responses to subsequent signals, so the early changes in neural activity that underlie short-term memory may render the neurone susceptible to later signals that induce a change in gene expression and long-term storage. There is in fact evidence that in some systems, neural morphogenesis is profoundly influenced by neural activity: learning may reflect the same (unknown) mechanism. Indeed changes in dendritic or synaptic morphology may be the basis for long-term memory.

An understanding of memory at this level will not, in Stevens's view, provide a complete understanding of the encoding of memories — any more than understanding the behaviour of transistors would help with the understanding of a computer program. But it could establish, for example, whether the process is reversible or not. It is possible that memories are for ever, and forgetting is just loss of access. Certainly this is to be expected from the developmental parallel, since differentiation is generally extremely stable, if not completely irreversible. There is, however, one notable case in which terminal differentiation entails the editing of the DNA and irrevocably limits the potential of the cell for further change. This is the case of the antibody-producing lymphocyte, in which recombination of the DNA is part of the basis for antibody diversity. Stevens, echoing Nottebohm's speculations, suggested that some similarly irreversible step might be made by the song cells of the canary HVc — so that the only way to change the repertoire would be by the loss of the old neurones and the addition of new ones.

It is however more likely (as he went on to emphasize) that versatility in memory depends not on the generation of diverse proteins by DNA recombination, but on the versatile deployment of a limited number of related families of receptor and channel proteins whose expression in different combinations confers on nerve cells the specialized properties of which so far we have such a limited understanding. Now that, with the cloning of the genes encoding the acetylcholine receptor[8], the first members of these protein families have yielded to recombinant DNA technology, dramatic advances in understanding their relationships and expression may not be far away. □

Seeing in colour

THE showpiece of the First McDonnell Conference on Higher Brain Function was the spectacular re-entry into research on colour vision of David Hubel (Harvard University), who, in a kingfisher shirt and scarlet tie, and with the assistance of Margaret Livingstone manipulating coloured lights, gave a personal demonstration of the importance of context in hue perception. The demonstration is simple (and in principle well known): bathe the outrageous shirt and tie in red light and the outrage vanishes: the shirt becomes black while the tie assumes the same pallid appearance as the speaker's face; similarly in blue light the vividness of the shirt is drained. This illustrates that human colour vision is not a simple function of the wavelength of light reaching the retina — as any reader who has a copy of *Nature* for 3 April 1980 (and has not lost the colour filters supplied with it) can check for himself.

Among the best explanations so far offered for the relative indifference of the visual system to the absolute wavelength of the stimulus is Land's retinex theory (discussed in the same issue of *Nature*[1]), according to which the sensation of colour is the outcome of interactions between neurones that respond selectively to lights of different wavelengths. Specifically, the theory predicts the existence of cells whose receptive fields are so organized that they respond maximally when the centre of the field is illuminated by light of a wavelength complementary to that illuminating the surround. A highly effective stimulus would thus be a red dot in a blue surround. Neurones responding to such stimuli are known as double-opponent colour cells and have been detected in very small numbers in the lateral geniculate nucleus of the cat[2], which has relatively poor colour vision, and in the visual cortex of the monkey[3], whose colour vision is comparable with man's. This anatomical difference between cat and monkey reflects the general rule that sophisticated sensory computations tend to be postponed to increasingly central sites with ascent up the phylogenetic tree.

Hubel and Livingstone have now illuminated a further species difference by locating the cortical double-opponent cells precisely in the patches, or 'blobs', of exceptionally high metabolic activity recently revealed by cytochrome oxidase staining in layers II and III[4,5]. These patches have two curious features (discussed in *Nature* by Swindale[6]). First, they contain cells that, unlike most visual cortical neurones, are not selective for stimulus orientation[7]; and second, they are absent from the visual cortex of the cat.

The absence of orientation selectivity could be explained if the patches represented areas of convergence of orientation columns[6] — and thus containing neurones responding to all orientations. But then why none in the cat? A possible answer to this question now suggests itself: the patches may, instead of representing converging orientation columns, be colour columns; and their absence in cats probably reflects the relative crudeness of feline colour vision.

Glucocorticoid regulation of protein processing and compartmentalization

Gary L. Firestone, Farhang Payvar & Keith R. Yamamoto

Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, California 94143, USA

Glucocorticoids appear to regulate the post-translational processing and compartmentalization of certain proteins in cultured rat hepatoma (HTC) cells. We have found that maturation of murine mammary tumour virus (MTV) proteins in infected HTC cells is hormone-dependent. Thus, MTV gene products may represent versatile and sensitive probes for examining cellular regulation of protein maturation.

THE location at which a given protein resides or acts is an integral and important aspect of gene expression. In general, proteins are 'targeted' or transported either during or after synthesis to particular intra- or extracellular compartments; the final gene product may be soluble in the cytoplasm, sequestered within specific intracellular organelles, inserted into particular cellular membranes, or secreted out of the cell. In addition, and perhaps related to this phenomenon of compartmentalization, many proteins are subject to one or more processing or chemical modification reactions including site-specific cleavage, phosphorylation and attachment of carbohydrates or lipids. Thus, the final location and biological activity of such mature proteins could in principle be regulated by modulating the appropriate post-translational events.

What signalling molecules might be involved in regulating gene expression at this level? In animal cells glucocorticoids and other steroid hormones act via specific intracellular receptors to elicit a broad range of responses in various target cells[1–3]; it has been established in some cases that the hormone–receptor complex directly stimulates transcription of the regulated loci. For example, when DNA encoding MTV is introduced into the genome of HTC cells, dexamethasone, a synthetic glucocorticoid, rapidly and selectively increases the rate of MTV RNA transcription[4,5]. Dexamethasone also regulates the expression of certain intracellular, cell surface and secreted proteins encoded by the HTC genome[6–13]; in these cases, the molecular processes under hormonal control have not been fully defined. Glucocorticoids could conceivably affect expression of some genes by stimulating or inhibiting transcription, others at a post-transcriptional event, and still others at multiple stages. To test this notion in detail requires the ability to detect specifically the DNA, RNA and proteins corresponding to a regulated gene and its products; unfortunately, such a combination of molecular hybridization and immunological reagents has not yet been reported for a glucocorticoid-controlled HTC cell gene.

In mammary tumour cells, MTV encodes two major polyproteins, each of which is specifically modified, cleaved and compartmentalized in an array of reactions that appear similar to those that effect maturation of various classes of cellular proteins[14–17]; specific antisera and cloned nucleic acid probes are available to monitor the precursor and mature MTV proteins, as well as the viral transcripts and genes. Therefore, MTV gene products in infected cells might be useful as general probes for putative glucocorticoid-regulated cellular functions that act post-translationally. Thus, we have used biochemical and genetic approaches to examine this possibility in an MTV-infected HTC cell derivative.

Effects of dexamethasone on MTV protein expression

Viral proteins were examined in M1.54, a cloned line of infected HTC cells containing 10 stably integrated MTV proviruses. As MTV RNA is produced at a basal rate in this line, and is strongly induced by dexamethasone[18,19], viral protein synthesis and maturation can be examined before and after hormone treatment. In addition, infectious MTV particles are not produced in this heterologous system[20], thereby precluding reintroduction of viral proteins into the cells via secondary infection.

In initial experiments, the full complement of MTV proteins produced by these infected rat cells was examined. M1.54 cells were labelled with ^{35}S-methionine for 12 h in the presence or absence of dexamethasone; hormone-treated cultures were exposed to dexamethasone for 24 h before labelling. Cellular and secreted proteins were solubilized in detergent-containing buffer and immunoprecipitated with an anti-MTV antiserum that detects all MTV gene products; to normalize for hormonal induction of viral transcripts, approximately equivalent amounts of immunoprecipitated radioactivity were then analysed on SDS-polyacrylamide gels. In hormone-treated M1.54 cells (Fig. 1*a*), 13 viral proteins were detected, ranging from molecular weight (M_r) 200,000 to 24,000, and comprising about 2% of the total labelled proteins. As shown below, the 74,000-M_r species actually represents two distinct viral gene products. In contrast, in the control cultures (Fig. 1*c*), seven of the MTV proteins were barely detectable or absent altogether relative to the remaining species, which were indistinguishable from those produced in dexamethasone-containing medium; the hormone-induced proteins are marked in Fig. 1 with arrows. Control experiments with preimmune sera (Fig. 1*b*, *d*) confirmed that all the proteins detected are MTV gene products.

Figure 1 shows that the 12-h labelling period enables even minor viral protein species to be detected; however, the possibility remains that the failure to observe certain of the proteins in the absence of dexamethasone is due to their relative instability, rather than their failure to accumulate. Therefore, cells were pulse-labelled with ^{35}S-methionine for 20 min then incubated for an additional 60- or 120-min 'chase' period in the presence of excess unlabelled methionine. The results (Fig. 2*a–f*) show that in the absence of dexamethasone, only the 74,000-M_r species is detected in either the pulse-labelled or pulse-chased material; in contrast, the 74,000-M_r protein pulse-labelled in dexamethasone-treated cultures is subsequently chased into the major viral products observed after long-term labelling (compare Figs 1*a* and 2*g–l*). While this experiment does not exclude extremely rapid degradation of the proteins in the control cultures, the simplest view is that they are produced only in the presence of hormone. Taken together, these results are consistent with the idea that glucocorticoids in some way regulate post-translational MTV protein maturation in M1.54 cells.

MTV transcripts in M1.54 cells

An alternative explanation for the hormonal effect on MTV protein expression is that dexamethasone-induced MTV transcripts differ qualitatively from those produced in the absence of hormone. Altered patterns of initiation and splicing or polyadenylation have been observed in other systems in response

0028–0836/82/460221—05$01 00

to changing physiological conditions or differentiation states[21,22]. By this view, hormonal regulation of transcription would account for qualitative and quantitative changes in MTV protein production.

Thus, MTV RNA was characterized biochemically and functionally. Total RNA from M1.54 cells cultured in the presence or absence of dexamethasone was translated *in vitro* in a rabbit reticulocyte lysate. Immunoprecipitation with anti-MTV antiserum and subsequent electrophoretic analysis revealed no effect of dexamethasone on the three MTV-specific polypeptides synthesized (Fig. 3*a–h*). In addition, cellular RNA from induced and uninduced cells was fractionated by agarose gel electrophoresis, transferred to nitrocellulose and hybridized with cloned MTV ^{32}P-DNA; the amount of MTV RNA in each gel sample was normalized. As shown in Fig. 3*i*, *j*, dexamethasone has no detectable effect on the sizes or relative stoichiometry of the two MTV RNA species produced in M1.54 cells, whereas no virus-specific sequences are detected in uninfected HTC cells (Fig. 3*k*, *l*). Further experiments have established that the hormone does not affect the site of initiation of viral RNA transcription in infected cells, nor does it alter either the sites or efficiencies of MTV RNA splicing and polyadenylation[23]. Taken together, these results show that the MTV RNA molecules produced in the presence and absence of dexamethasone in M1.54 cells are qualitatively and functionally identical, and that any effect of glucocorticoids on viral protein maturation probably occurs co- or post-translationally. Independent support for this view is provided by experiments demonstrating that an MTV precursor protein pulse-labelled with ^{35}S-methionine in untreated M1.54 cells is subsequently matured when dexamethasone is added to the medium during the chase period (G.L.F., unpublished result).

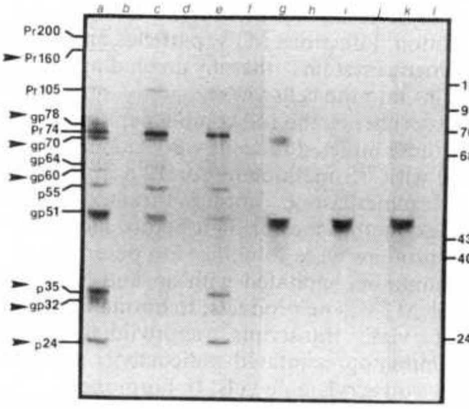

Fig. 1 MTV proteins produced by M1.54, and by a complement-resistant derivative, CR4. M1.54 and CR4 cells (5×10^6) were labelled with 100 µCi ^{35}S-methionine for 12 h in 4 ml methionine-deficient Dulbecco's modified Eagle's medium supplemented with 1% dialysed fetal calf serum; hormone-treated cultures were incubated with 1 µM dexamethasone 24 h before as well as during the radiolabelling period. The cells were collected by centrifugation (600*g*, 3 min), and the supernatant was re-centrifuged (10,000*g*, 10 min) to remove cell debris. The cell pellets were homogenized in 1 ml of 1% Triton X-100, 0.5% sodium deoxycholate, 5 mM EDTA, 250 mM NaCl, 25 mM Tris-HCl, *p*H 7.5 (solubilization buffer) and the solubilized proteins collected as the supernatant after centrifugation at 20,000*g* for 20 min at 4 °C. The medium was adjusted to 1% Triton X-100, 0.5% sodium deoxycholate, 5 mM EDTA just before immunoprecipitation. Viral proteins were immunoprecipitated by a modification of the staphylococcal protein A-antibody adsorption procedure[41]; 10-fold more extract from uninduced cells was immunoadsorbed, thereby approximately equalizing the amounts of MTV proteins analysed per sample. The detergent-solubilized fractions (300–500 µl) were preadsorbed with 10 µl of 10% fixed *Staphylococcus aureus* (Staph A) for 15 min at room temperature. After removal of Staph A by centrifugation, 1 µl of either anti-MTV rabbit serum (lanes *a*, *c*, *e*, *g*, *i*, *k*) or preimmune serum (lanes *b*, *d*, *f*, *h*, *j*, *l*) was added; antisera were given by R. D. Cardiff and co-workers[42]. The mixtures were incubated at room temperature for 15 min before addition of 10 µl of 10% fixed Staph A that had been preadsorbed with unlabelled cell extracts. After incubation for 5 min, the Staph A was centrifuged through 1 M sucrose in solubilization buffer, washed once in solubilization buffer and then once in 5 mM EDTA, 10 mM Tris-HCl, *p*H 7.5 (buffer B). Nonspecific binding of cellular radiolabelled proteins was significantly reduced by a second immunoprecipitation of the viral antigens. The immunoadsorbed antigens were eluted from the Staph A-associated IgG by incubating the Staph A pellets with 30 µl of 2% SDS at 37 °C for 20 min. After removing the Staph A by centrifugation, the eluted viral antigens were added to 400 µl of solubilization buffer containing 0.8 µl of antiserum and incubated at room temperature for 15 min. Fixed Staph A (10 µl of a 10% suspension) was added, incubated for 5 min and collected by centrifugation. The pellets were washed once in solubilization buffer and once in buffer B. Finally, the immunoadsorbed MTV proteins were eluted from the Staph A in SDS sample buffer, fractionated by SDS-polyacrylamide gel electrophoresis[43], and visualized by fluorography[44]. The figure shows cellular MTV proteins from hormone-treated M1.54 (*a*, *b*), uninduced M1.54 (*c*, *d*) and hormone-treated CR4 (*e*, *f*). Arrows denote the viral gene products produced in a hormone-dependent manner in M1.54. Also shown are secreted MTV proteins from hormone-treated M1.54 (*g*, *h*), uninduced M1.54 (*h*, *i*) and hormone-treated CR4 (*k*, *l*). The molecular weight markers are: β-galactosidase (M_r 120,000; 120K), phosphorylase *a* (94K), conalbumin (76K), bovine serum albumin (BSA; 68K), ovalbumin (43K), aldolase (40K) and chymotrypsinogen (24K).

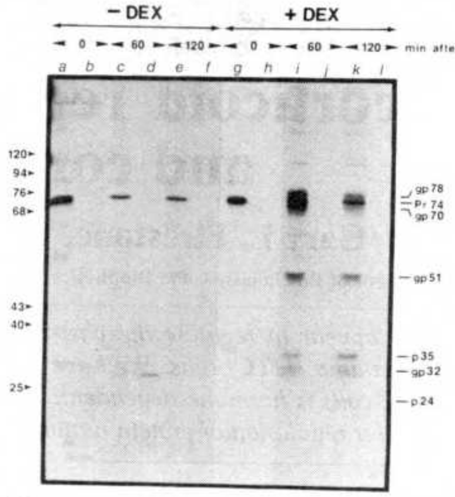

Fig. 2 ^{35}S-methionine MTV proteins produced by M1.54 during pulse and subsequent chase. M1.54 cells (10^7) were labelled at 37 °C for 20 min in medium containing 100 µCi ml^{-1} ^{35}S-methionine; cultures were either collected immediately or incubated for an additional 60 or 120 min in chase medium containing 2 mM unlabelled methionine. Hormone treatment, preparation of extracts, immunoprecipitation, gel electrophoresis and molecular weight standards were as described in Fig. 1 legend. Immunoprecipitation was with anti-MTV rabbit serum (lanes *a*, *c*, *e*, *g*, *i*, *k*) or preimmune serum (lanes *b*, *d*, *f*, *h*, *j*, *l*). *a–f*, Cellular MTV protein from uninduced M1.54 cells that were: *a*, *b*, pulse-labelled for 20 min; *c*, *d*, pulse-labelled and chased for 60 min; and *e*, *f*, pulse-labelled and chased for 120 min. *g–l*, MTV proteins from dexamethasone-treated M1.54 cultures that were: *g*, *h*, pulse-labelled for 20 min; *i*, *j*, pulse-labelled and chased for 60 min; and *k*, *l*, pulse-labelled and chased for 120 min.

Regulation of MTV phosphoprotein maturation in M1.54 cells

Two MTV transcripts similar to those described here are detected in virion-producing mouse mammary tumour cell lines; one specifies core proteins encoded by the *gag* gene, while the other specifies envelope proteins encoded by the *env* gene[24]. Each precursor acquires characteristic modifications; the *gag* polyproteins are phosphoproteins whereas the *env* polyproteins are glycoproteins. In both cases, the polyproteins are subsequently processed into several mature species. Thus, monospecific antibodies directed against either the MTV envelope glycoproteins or the core phosphoproteins were used to identify further the MTV proteins produced in M1.54 cells. This showed that the mature *gag*-encoded species are p55, p35 and p24, and that the mature *env*-encoded species are gp78, gp70, gp64, gp60, gp51 and gp32 (see Fig. 1 and below). In addition, the major precursors encoded by both the *gag* and *env* genes are M_r 74,000, and are designated as Pr74 in Fig. 1.

Immunoprecipitation with the monospecific antibodies also revealed that all the viral phosphoproteins in M1.54 are *gag*-related (data not shown); therefore, ^{32}P-phosphate was used to label selectively the *gag* proteins. Figure 4 shows that

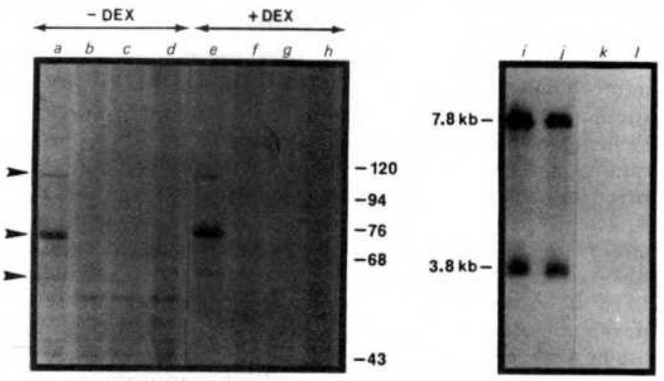

Fig. 3 Functional and biochemical analysis of MTV RNA. Total RNA, isolated from control or dexamethasone-treated (1 μM, 24 h) cultures of M1.54 and HTC by a combination of the guanidinium thiocyanate cell lysis[45] and CsCl centrifugation[46] methods, was subjected to *in vitro* translation (*a–h*) and size fractionation (*i-l*). For cell-free protein synthesis, typical 50-μl reaction mixtures contained 40 μCi ^{35}S-methionine (~1,000 Ci mmol^{-1}), 35 μl of nuclease-treated rabbit reticulocyte lysate[47,48] and 10 μg of total RNA. After 90 min at 37 °C, the incubation mixtures were added to 400 μl solubilization buffer, immunoprecipitated and fractionated in SDS gels together with molecular weight standards as in Fig. 1. Immunoprecipitations were carried out with anti-MTV serum (*a, c, e, g*) or preimmune serum (*b, d, f, h*); RNA was from uninduced M1.54 (*a, b*) and HTC (*c, d*) cells, and from hormone-induced M1.54 (*e, f*) and HTC (*g, h*) cells. Immunoprecipitations were done using 10-fold more translation products from uninduced cell RNA in order to approximately equalize levels of immunoprecipitated MTV polypeptides. Arrows denote MTV-specific *in vitro* translation products. RNA was size-fractionated by electrophoresis in formaldehyde–agarose gels[49]; 10-fold more total RNA from uninduced cells (5 μg) was analysed relative to RNA from hormone-induced cells (0.5 μg). RNA was heated to 68 °C for 5 min in 50% formamide, 2.2 M formaldehyde in running buffer (1 mM EDTA, 5 mM sodium acetate, 10 mM sodium phosphate, *p*H 7.0), then electrophoresed in 0.8% agarose gels containing 2.2 M formaldehyde in running buffer. The fractionated RNA was transferred to nitrocellulose filters in 20 × SSC (1 × SSC is 150 mM NaCl, 15 mM sodium citrate), and the filters were baked at 80 °C for 2 h *in vacuo* and incubated at 42 °C for 16 h in annealing mix [3 × SSC, 50% formamide, 50 mg ml^{-1} sheared denatured salmon sperm DNA, 5 × Denhardt's solution (1 × Denhardt's is 0.02% (w/v) each of BSA, polyvinyl pyrrolidone and Ficoll)]. The filters were then hybridized (18 h at 42 °C) with cloned MTV ^{32}P-DNA (1–3 × 10^{8} d.p.m. μg^{-1}) in annealing mix containing 10% dextran sulphate, washed three times for 20 min in 0.1 × SSC, 0.1% SDS at 50 °C and subjected to autoradiography at −70 °C. *i*, RNA from hormone-treated M1.54; *j*, RNA from uninduced M1.54; *k*, RNA from hormone-treated HTC; and *l*, RNA from uninduced HTC cells.

dexamethasone significantly alters viral phosphoprotein maturation in M1.54. The predominant phosphorylated species produced in the absence of dexamethasone is Pr74^{gag}; hormonal treatment results in the production of low levels of a second phosphorylated *gag* polyprotein, p76, and two presumptive maturation products, p35 and p24. The constitutively produced *gag* product, p55 (Fig. 1*a*, *c*), is not detectably phosphorylated. One interpretation of these data is that dexamethasone potentiates the proteolytic cleavage of one or both phosphorylated *gag* polyproteins into two smaller phosphorylated species; alternatively, the hormone might stimulate Pr74 phosphorylation to the p76 species, thereby permitting subsequent cleavage.

Two phosphorylated MTV *gag* polyproteins have also been detected in a line of mouse thymic lymphoma cells. In this case, it was found that phosphatase digestion of the larger species yielded the smaller product, implying that the larger species may reflect additional phosphorylation of the smaller[25]. We have not yet determined whether the dexamethasone-induced appearance of p76 in M1.54 cells involves a second phosphorylation of Pr74, or whether p76 is required for the apparent specific proteolytic processing of the polyprotein.

Regulation of MTV glycoprotein maturation in M1.54 cells

As covalent attachment of mannose-containing glycosylamine-linked oligosacharide side chains is one of the initial steps in cellular glycoprotein synthesis, [2-^{3}H]mannose provides a sensitive tracer for monitoring MTV glycoprotein maturation[26]. The time course of the process was examined by exposing control and hormone-induced M1.54 cultures to [2-^{3}H]mannose for 20 min, followed by additional incubation in the presence of excess unlabelled mannose. At various times during this pulse-chase, the viral proteins were immunoprecipitated with anti-MTV antiserum, fractionated by electrophoresis and visualized by fluorography.

Figure 5*a*, *c* shows that M1.54 cells initially synthesize a 74,000-M_r precursor glycoprotein, Pr74^{env}, both in the presence and absence of dexamethasone. After a 150-min chase period, the hormone-treated cells (Fig. 5*b*) appear to have processed Pr74^{env} into each of the known glycoprotein products (gp78, gp70, gp64, gp60, gp51 and gp32), while a stable form of Pr74^{env} persists. In contrast, the chased control cultures (Fig. 5*d*) produce very low levels of gp78 relative to Pr74^{env}, and yield no detectable gp70, gp60 or gp32; significantly, the uninduced cells do produce gp51 as an apparent Pr74^{env} processing product. Thus, Pr74^{env} seems to be processed in at least two distinct ways: a constitutive reaction giving a single product, and a hormone-inducible pathway resulting in a more complex mixture of species.

Localization of MTV glycoproteins was examined in separate experiments. Plasma membrane proteins were labelled by lactoperoxidase-mediated iodination of intact hormone-treated M1.54 cells; immunoprecipitation revealed that gp78, gp70, gp51 and gp32 are located at the cell surface[27]. When ^{35}S-methionine-labelled extracellular proteins were reacted with this same antiserum, we observed that hormone-treated cells secreted gp51 and gp70 (Fig. 1g, h); glycosylation of the secreted viral species was confirmed by immunoprecipitation of [2-^{3}H]mannose-labelled extracellular proteins (data not shown). In fully induced M1.54 cells, the secreted gp51 and gp70 represent ~90% of the MTV glycoproteins that accumulate over a 24-h period. Figure 1 *l*, *j* shows that uninduced cells secrete much lower levels of gp70 than gp51. Thus, gp51 maturation seems hormone-independent while the production and secretion of gp70 is glucocorticoid-regulated.

Isolation of mutants defective in MTV protein maturation

Our results are consistent with the view that dexamethasone affects a spectrum of protein maturation reactions that alter

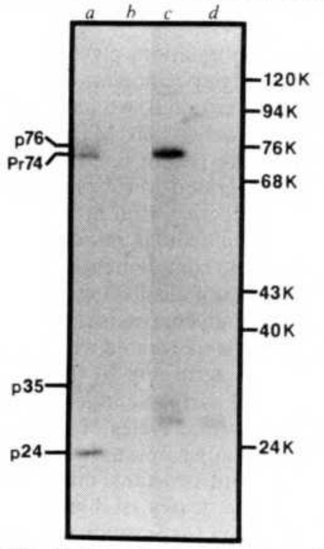

Fig. 4 Glucocorticoid-dependent maturation of MTV phosphoproteins. Dexamethasone-treated or control cultures of M1.54 were labelled with 1 mCi ^{32}P-phosphate for 12 h in phosphate-deficient medium; dexamethasone treatment was as described in Fig. 1 legend. The cell-associated MTV proteins were detergent-solubilized, immunoprecipitated and analysed as described in Fig. 1 legend; approximately 10-fold more extract from uninduced cells was used in the immunoprecipitations. *a*, Hormone-treated cells and anti-MTV serum; *b*, hormone-treated cells and preimmune serum; *c*, uninduced cells and anti-MTV serum; *d*, uninduced cells and preimmune serum. Molecular weight standards are as in Fig. 1.

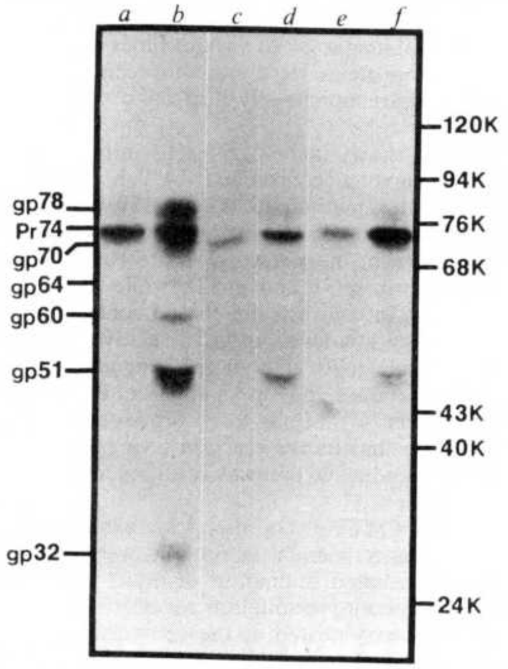

Fig. 5 MTV glycoprotein expression in M1.54 and CR4 cells. Cells were pulse-labelled at 37 °C for 20 min with 200 μCi [2-^{3}H]mannose and then incubated in the presence of 25 mM unlabelled mannose for further 150 min; hormone treatment was as described in Fig. 1 legend. Cell pellets were detergent-solubilized, immunoprecipitated and the viral glycoproteins analysed as described in Fig. 1 legend. Approximately 10-fold more material from uninduced cells was used for the immunoprecipitations. All lanes show immunoprecipitations with anti-MTV serum; parallel immunoprecipitations with preimmune serum demonstrated that all the glycoproteins detected are MTV-specific (data not shown). *a*, Pulse-labelled hormone-induced M1.54; *b*, 150 min chase of *a*; *c*, pulse-labelled uninduced M1.54; *d*, 150 min chase of *c*; *e*, pulse-labelled hormone-induced CR4; *f*, 150 min chase of *e*. the efficiency of phosphorylation, glycosylation, cleavage and compartmentalization of a specific class of proteins. To examine these processes in greater detail, we have isolated mutant cell lines carrying genetic defects in MTV protein maturation. M1.54 was chosen as the parent line in our initial selections; this line carries 10 integrated MTV proviruses, thus it seems likely that mutations affecting viral protein maturation in this line will reflect lesions in cellular rather than viral sequences.

For these experiments, complement-mediated cytolysis was used to select mutants not displaying hormone-induced cell surface-associated MTV glycoproteins. M1.54 cells exposed to dexamethasone for 24 h were treated with anti-MTV antiserum and rabbit complement according to the method of Kabat *et al.*[28]; cells carrying viral surface antigens are rapidly lysed by the complement. After three cycles of selection and regrowth of surviving cells, the putative mutants were cloned and isolated.

One such complement-resistant mutant, CR4, expresses approximately wild-type levels of hormone-inducible MTV RNA[27], but is defective in the hormone-induced processing of $\mathrm{Pr74}^{\mathrm{env}}$. In the presence of dexamethasone, MTV glycoprotein processing in CR4 seems similar to the uninduced parent M1.54 cells; thus, CR4 cells essentially lack intracellular gp78, gp70 and gp32 (Fig. 1*e*, *f*; Fig. 5*e*, *f*), as well as secreted gp70 (Fig. 1*k*, *l*), whereas gp51 is produced competently and secreted. Interestingly, MTV phosphoprotein maturation seems to be unimpaired in CR4 cells (Fig. 1*e*, *f*). This genetic uncoupling of the glucocorticoid-dependent processing of phosphoproteins and glycoproteins is consistent with the view that at least two distinct protein maturation events may be hormonally regulated in HTC cells.

Conclusions and implications

Dexamethasone has striking effects on the expression of intracellular and extracellular MTV proteins in M1.54; Fig. 6 summarizes our view of the overall pattern of maturation. The dexamethasone-mediated stimulation of MTV RNA production suggests a trivial explanation for our observations: the precursor polyprotein levels may simply be increased sufficiently to allow their recognition by pre-existing maturation enzymes. However, a complement-resistant mutant of M1.54 to be described elsewhere[27] argues against this possibility, as MTV RNA and precursor protein levels are not increased by dexamethasone in that line, yet the cell surface glycoproteins are nevertheless matured.

Assuming that the processing and compartmentalization of the viral proteins is mediated by cellular components, these results suggest that glucocorticoid hormones may regulate HTC cell gene expression post-translationally. Conceivably, this mode of control by glucocorticoids could be of general significance for steroid hormonal regulation of developmental and physiological processes. It has been clearly established in a few cases that steroids affect the rate of specific mRNA transcription or turnover[4,5,29-31]. The present work now implies that these same signalling molecules can dramatically affect the expression of a gene long after it has been transcribed. In this regard, it is interesting to note that dexamethasone regulates the expression of MTV gene products in M1.54 cells both at the transcriptional and post-transcriptional levels.

Our genetic and biochemical evidence suggests that at least two post-translational maturation pathways are glucocorticoid-regulated, one controlling glycoprotein processing and compartmentalization, and another involved in phosphoprotein maturation. Recent results indicate that MTV glycoprotein maturation seems similar to that described for certain cellular proteins and for the G-protein of vesicular stomatitis virus[32]. Thus, $\mathrm{Pr74}^{\mathrm{env}}$ contains incomplete oligosaccharide side chains, as they are cleaved by endo-β-*N*-acetylglucosaminidase H (endo H)[33], while its secreted or plasma membrane-associated maturation products (gp78, gp70, gp51 and gp32) contain complete oligosaccharide side chains, as judged by their resistance to endo H digestion[33]. In addition, the cell surface forms of

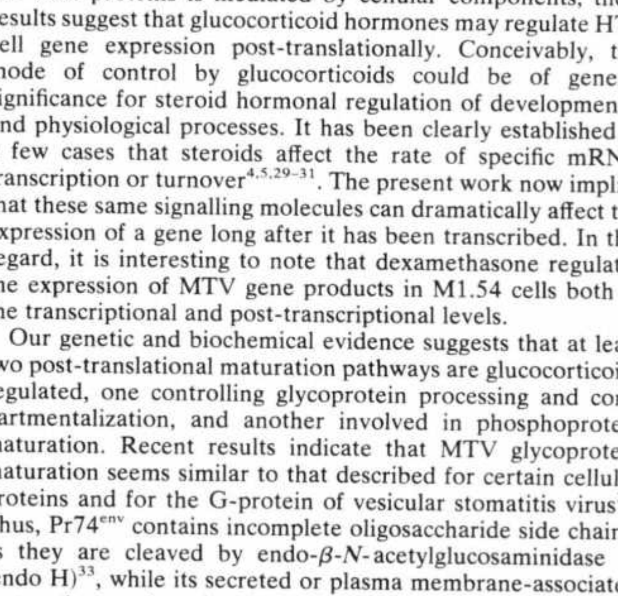

Fig. 6 Proposed pathways of MTV protein maturation in M1.54 cells. The *gag*-encoded precursor polyprotein is translated from 7.8-kilobase (kb) MTV RNA[24,50] and is differentially processed in the presence (+dex) and absence (−dex) of dexamethasone. Similarly, the *env*-encoded precursor glycopolyprotein is translated from 3.8-kb MTV RNA[24,46] and then processed in a hormone-dependent manner. s, Secreted glycoproteins; m, plasma membrane-associated species. Several larger precursors (Pr200, Pr160, Pr105) are also detected (see Fig. 1); these minor species are not shown in this diagram.

gp78, gp70 and gp32 are modified by the attachment of palmitic acid (G.L.F., unpublished result).

Clearly, there are many potential targets for hormone regulation of protein maturation. For example, glycosyltransferases, glycosidases, proteases or protein kinases that recognize the viral proteins as substrates could be hormone-induced at transcriptional or post-transcriptional levels. In fact, steroid hormones have been reported to alter the apparent activities or concentrations of such enzymes, but specific substrates and direct molecular and genetic approaches were not available in these cases[34–38]. Regulation of protein processing activities could affect not only the 'targeting' of proteins to particular locations, but might also change the stability of the polyprotein precursors. Another possibility is that dexamethasone alters the expression of 'compartmentalization factors' analogous to those involved in intracellular membrane localization of β-glucuronidase in kidney epithelia[39], or to β_2-microglobulin-mediated membrane insertion of histocompatibility locus antigens[40].

In any case, it is apparent that glucocorticoids are capable of regulating post-translational aspects of gene expression. These hormonal effects were detected in the present studies by exploiting MTV gene products as specific probes within HTC cells. As MTV appears to infect cultured cells from a broad range of species and tissue types, it may be possible to use these genes to test the generality of these protein maturation regulatory phenomena. Recently, we have detected the dexamethasone-dependent production of an MTV phosphopolyprotein in GR cells, a virion-producing mouse mammary carcinoma cell line (G.L.F., unpublished result). Given these sensitive molecular probes, it may be possible to elucidate the mechanisms by which glucocorticoids affect protein maturation.

We thank L. J. T. Young and R. D. Cardiff (Department of Pathology, School of Medicine, University of California, Davis) for their gifts of antisera used in this study, and H. Bourne, Z. Hall, R. Kelly and colleagues in our laboratory for helpful comments on the manuscript. G.L.F. was supported by a postdoctoral fellowship from the Cystic Fibrosis Foundation, F.P. by a postdoctoral fellowship from the Damon Runyon-Walter Winchell Cancer Research Fund, and K.R.Y. by a NIH Research Career Development Award. Research support was from the NCI (CA20535) and the American Cancer Society (RD122).

Recombination between dispersed serine tRNA genes in *Schizosaccharomyces pombe*

Peter Munz, Hanspeter Amstutz, Jürg Kohli & Urs Leupold

Institute of General Microbiology, University of Bern, Baltzer-Strasse 4, CH-3012 Bern, Switzerland

During meiosis in fission yeast, transfer of genetic information occurs between tRNA genes of related sequence even when they are located on different chromosomes. This process of intergenic conversion has been analysed with the help of nonsense suppressors derived from three unlinked serine tRNA genes. In their wild-type form two of the genes code for $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCA}}$, *the third for* $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCG}}$. *We demonstrate the transfer of anticodon and adjacent intron sequences between two tRNA genes coding for different serine isoacceptors.*

THE first gene families studied in detail were the tandemly arranged ribosomal RNA genes. To explain the striking sequence conservation between individual copies in a given species, several rectification models have been proposed[1]. One of these mechanisms, unequal crossing-over, has been documented experimentally for the rRNA genes in *Saccharomyces cerevisiae*[2,3] and *Salmonella typhimurium*[4]. Meanwhile, it has been found that rectification mechanisms must also be responsible for the concerted evolution[5] observed in other gene families which are not necessarily arranged in tandem, such as the repeated globin genes[5,6] and immunoglobulin genes[7]. Further examples include separated blocks of tandemly repeated genes that are located on non-homologous chromosomes, that is, rRNA genes[8,9] and repetitive sequences of unknown function[10]. Finally, concerted evolution has also been observed among the completely dispersed 5S rRNA genes in *Neurospora*

0028–0836/82/460225—07$01 00

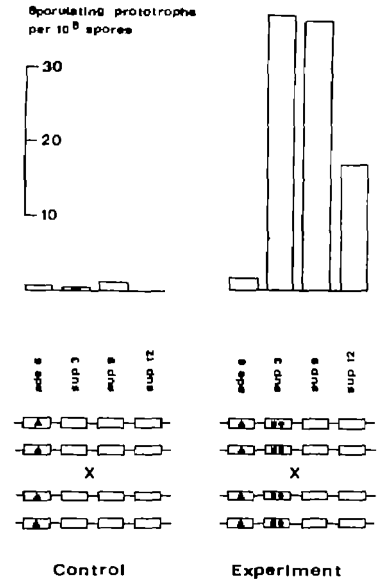

Fig. 1 Frequencies of prototrophs in experimental selfings and controls. The contrasting results obtained from the control cross no. 13 and the experimental cross no. 15 are shown (see Table 1). The gene symbols apply to both the upper and lower parts of the figure. The lower part depicts the crosses between diploid parents. This schematic representation does not reflect the known linkage relationships between the genes concerned. In both cases all *ade6* loci were occupied by a suppressible nonsense allele (*ade6-704*, ▲). The only difference between the two crosses concerns the *sup3* genes: in the control all were wild type; the experimental cross was homozygous for the *sup3-UGA,r36* allele, combining suppressor active anticodon information (■) with a secondary inactivating lesion (*r36*, ●). All other suppressor loci were occupied by wild-type alleles in both crosses. The upper part gives the frequency of sporulating prototrophic revertants owing their prototrophy to a reversion of the *ade6* mutant gene or to an active suppressor as indicated. Overall frequencies would be 50% higher because only sporulating revertants heterozygous for mating type have been analysed. We assume that the pattern of events is the same for the sporulating (2/3) and the non-sporulating (1/3) population, but under any assumption the marked increase of *sup3-UGA*, *sup9-UGA* and *sup12-UGA* events in the experimental situation, compared with the control, would persist.

crassa[11]. Molecular mechanisms proposed to contribute to the concerted evolution not only of tandemly arranged but also of dispersed repeated genes include gene transposition[11] and intergenic conversion[6,7,9,12,13].

Intergenic conversion implies an information transfer between nonallelic genes of related nucleotide sequence by a mechanism analogous to that proposed for recombination of allelic genes[14]. Within a family of directly repeated genes, intergenic conversion without associated crossing-over does not lead to copy-number variation. Therefore, gene duplications and deletions which are the consequence of models based solely on unequal crossing-over do not necessarily occur during concerted evolution. In the case of dispersed repeated genes, intergenic conversion may well be the main mechanism permitting co-evolution. That intergenic conversion really occurs in mitosis and meiosis has been demonstrated in *S. cerevisiae* for pairs of mutationally inactivated protein structural genes[15–17]. In these studies a second copy of a given gene was integrated at various sites in the genome by transformation and in those cases in which the two genes carried different mutations, fully active genes were obtained by recombination. The two cytochrome *c* genes in *S. cerevisiae* are examples of naturally occurring genes with related sequences mapping on different chromosomes. In this case, DNA sequencing of revertants of several mutations revealed the import of blocks of wild-type sequence from the corresponding non-identical gene[18].

Transfer RNA genes are widely dispersed in the genomes of most organisms. Nevertheless, multiple genes coding for a specific isoacceptor very often maintain one common nucleotide sequence in the segments that code for the mature tRNA. We previously reported genetic evidence that intergenic conversion occurs between dispersed serine tRNA genes in *Schizosaccharomyces pombe*[19]. Here we present further genetic and physical data indicating that information transfer occurs spontaneously during meiosis between three unlinked serine tRNA genes that code in their wild-type form for two different serine isoacceptor tRNAs. We show that the different anticodons and also adjacent diverging sequences of the introns may be exchanged between these tRNA genes.

The genes *sup3* on chromosome I and *sup9* on chromosome III are the only ones that in their wild-type form encode the UCA reading isoacceptor with the anticodon U*GA (where U* is a modified uridine)[20]. Both have been sequenced recently (ref. 21 and D. Söll, personal communication) and are also available as opal (UGA) suppressor alleles coding for tRNAs with the anticodon U*CA[22]. The single gene *sup12* on chromosome I codes in its wild-type form for the UCG reading serine tRNA with the anticodon CGA and has been sequenced earlier[23]. All three genes are organized in a unique way (Fig. 4): the serine tRNA coding sequences are identical with the exception of one differing base pair corresponding to the tip of the tRNA extra loop and of the obvious differences between the anticodon sequences. The genes *sup3* and *sup9* ($\text{tRNA}^{\text{Ser}}_{\text{UCA}}$) carry identical introns of 15 base pairs (bp) which differ at six positions from the 16-bp intron of *sup12* ($\text{tRNA}^{\text{Ser}}_{\text{UCG}}$). On the 3′ side of each of these serine tRNA genes follows a completely conserved DNA sequence comprising a spacer of 7 bp and a gene coding for initiator tRNA^{Met}. Thus, the region of sequence homology between the three DNA segments is ~200 nucleotides long including a few partially conserved base pairs in the flanking regions.

Informational transfer between non-linked serine tRNA genes is documented genetically by comparing two types of crosses. In type I, the control, the two parents are identical, except for mating-type, and carry a nonsense mutation in a

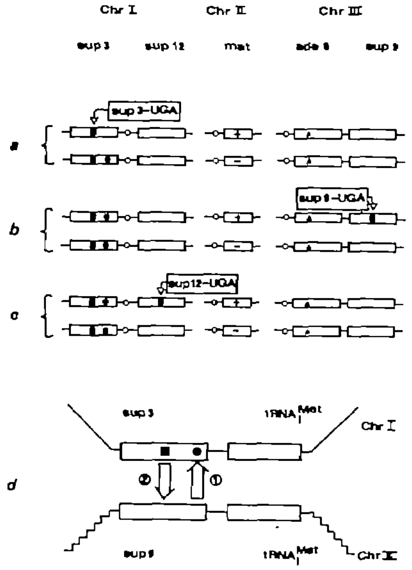

Fig. 2 Import and export of genetic information by intergenic conversion. The genotypes of the predominant classes of prototrophs obtained from cross no. 15 are depicted. *sup3* and *sup12* are on chromosome I, yet genetically not closely linked with each other. *mat* refers to the mating-type locus on chromosome II. *ade6* and *sup9* are located on chromosome III[26]. Empty rectangles represent wild-type genes, symbols as in Fig. 1. *a–c*, Prototrophic diploids owing their adenine independence to one copy of the dominant and efficient suppressors *sup3-UGA*, *sup9-UGA* and *sup12-UGA*, respectively. *d*, A schematic representation of the mechanism thought to generate the vast majority of these prototrophic revertants. For example, the wild-type gene *sup9*$^+$ may interact during meiosis with the related partner *sup3-UGA,r36*. A single-site conversion replacing the inactivating *r36* site, but not the anticodon site, of the doubly marked *sup3* gene by a corresponding wild-type segment from *sup9*$^+$ leads to an active *sup3-UGA* allele (1). On the other hand, transfer of the suppressor active anticodon sequence, divorced from *r36*, to the wild-type gene *sup9*$^+$ will generate a *sup9-UGA* suppressor (2). As in conversion involving allelic genes the donating partner is found to emerge unchanged from the interaction. Entirely analogous events are postulated to occur also between *sup3-UGA,r36* and *sup12*$^+$

biosynthetic gene. They are thus auxotrophic. In type II, the experimental situation, the parents carry in addition an identical inactive suppressor allele at corresponding loci. These alleles have suppressor-active anticodon information (obtained by mutation in a first step) but are prevented from suppressing the background nonsense mutation due to a secondary intragenic lesion (obtained in a second mutational step). They are thus also auxotrophic. In both cases prototrophic revertants can be obtained by plating progeny spores on media lacking the growth factor whose biosynthesis is prevented by the nonsense mutation. Type I gives few revertants which result from reversion of the nonsense mutation and from forward mutations at suppressor loci in comparable frequencies. This represents the mutational background. Type II shows a dramatic increase in reversion frequency. The surplus events occur both in the suppressor gene that was originally doubly marked in the parents of the cross and in the two remaining serine tRNA genes which were originally present in wild-type form. Mutation cannot explain this result. Also, recombination between the doubly-marked suppressor genes of the parents does not lead to an active suppressor because these genes are identical. Instead, we propose that non-allelic members of this gene family may interact and exchange information in a process analogous to gene conversion between allelic genes. Non-reciprocal information transfer may occur in either direction when the doubly-marked gene interacts with a wild-type member of the family: replacement of the secondary lesion by wild-type information leads to an active suppressor in the former, transfer of the suppressor-active anticodon information into the wild-type gene leads to an active suppressor in the latter. Physical analysis has corroborated this interpretation, as restriction mapping and DNA sequencing show that genes obtained by this process of intergenic conversion may differ from the original copy at several non-adjacent sites, reflecting the transfer of DNA segments.

Two known suppressor tRNA genes import information from non-allelic genes

To detect rare intergenic convertants an experimental system is needed that allows discrimination against events caused by recombination between allelic genes. This we have achieved by carrying out homozygous crosses, that is, selfings of strains carrying inactivated suppressors.

A first series of experiments involved the selfing of auxotrophic haploid strains and the analysis of the rare prototrophic revertants obtained among the progeny spores. The results are summarized in the first part of Table 1 (expts 1–12). Strains carrying either the UGA nonsense mutation *ade6-704* or *ade1-40* in combination with wild-type genes at all suppressor loci served as controls (expts 1 and 8). The experimental strains carried, on the background of one or the other of these nonsense mutations, inactive suppressor alleles combining suppressor active anticodon information with a secondary inactivating lesion[24] (*sup3-UGA,rX*: expts 2–7; *sup9-UGA,rX*: expts 9–12). It is obvious that the reversion frequency is much higher in the experimental selfings than in the controls. Furthermore, the prototrophy of the revertants obtained from the experi-

Strains 1–7 are of general constitution h^{90} *ade6-704 sup3* and strains 8–12 of constitution h^{90} *ade1-40 sup9* with the particular suppressor alleles indicated. They are haploid and homothallic, that is, self-sporulating. In sporulating conditions they produce diploid zygotes leading on meiosis to asci containing four haploid and homothallic spores. Thus, this procedure is equivalent to crossing two heterothallic strains differing only at the mating-type locus (h^+ and h^-). *ade6-704* and *ade1-40* are both suppressible UGA nonsense mutations which lead, when not suppressed, to an adenine requirement and, in the case of *ade6-704*, to the formation of a characteristic red pigment in colonies grown on media with low adenine concentrations such as yeast extract agar. Crosses 13–15 involve two diploid parents each and are of the general type (h^+/h^+ *ade6-704/ade6-704 sup3/sup3*)×(h^-/h^- *ade6-704/ade6-704 sup3/sup3*) with particular *sup3* alleles indicated. The two parents of any of these three crosses are different only with respect to the mating-type locus. Such matings result in tetraploid zygotes which after meiosis produce asci with four diploid spores. Two-thirds of these spores are of heterozygous mating-type constitution (h^+/h^-) and give rise to diploid clones, which in turn will sporulate in appropriate conditions producing haploid progeny. They are directly amenable to genetic testing, in contrast to the last third which is stable and of constitution h^+/h^+ and h^-/h^-, respectively. The suppressor alleles involved in these selfings are either wild-type or double-mutant alleles combining suppressor active anticodon information with a secondary inactivating lesion elsewhere in the suppressor gene[24]. Selfings 1, 8 and 13 represent controls and are alike in the sense that only wild-type alleles are involved at all suppressor loci concerned. Selfings were done on malt extract agar slants supplemented with adenine (8 days, 25 °C). The sporulated cultures were suspended in water, treated overnight with snail digestive juice to inactivate remaining vegetative cells, washed and resuspended in 5 ml water. 4 ml of each suspension were distributed on 20 minimal agar plates in order to select prototrophic revertants (selfings 1–12: 7 days, 30 °C; selfings 13–15: 9 days, 25 °C). Aliquots of appropriate dilutions were spread on yeast extract agar for total spore counts. The number of independent repeats of a particular selfing is indicated Pooled data are given as no cases of extreme fluctuation were observed A sample of the revertants was analysed to determine the factor responsible for prototrophy. In the case of selfings 2–7 and 9–12 some 70 randomly chosen revertants were analysed per selfing. These were taken in approximately equal numbers from the three repeats. The sample in selfings 13–15 consisted of all sporulating revertants obtained. The nature of these revertants was assessed in crosses with a set of five haploid tester strains: a wild-type strain and four mutant strains each of which carried one of four efficient suppressors on the background of *ade6-704*. The haploid revertants from selfings 1–12 could be directly crossed to the testers. From the sporulating diploid revertants of selfings 13–15, 8 tetrads were analysed per revertant strain. Class I isolates produced two prototrophic and two adenine-dependent segregants per tetrad. One prototrophic haploid segregant was used for testing. Class II isolates were observed only in selfings 14 and 15 and gave two lethal and two auxotrophic segregants per tetrad. They could be subdivided in classes IIA and IIB as the lethality in the former class was due to a mutant *sup3* background (*sup3-UGA,rX*) and haplo-vital prototrophic derivatives, amenable to testing, could be obtained on replacement of *sup3-UGA,rX* by *sup3*$^+$. The lethality in the latter class could not be removed by this procedure. Crosses between the revertants and the five testers were performed and haploid progeny spores plated on yeast extract agar. If the progeny colonies of a particular test cross were only white, it was concluded that the strain under study and the tester carried the same determinant responsible for prototrophy (the same suppressors in the case of suppressor testers, an *ade*$^+$ gene in the case of the wild-type tester). This positive indication of allelism was complemented by analysing at least one of the four remaining crosses with the same revertant. Apart from the special situation described below, such crosses gave white and red colonies, the latter being suppressor free *ade6-704* recombinants. In the case of revertants originating from selfings involving *ade1-40* (nos 8–12) progeny from crosses with the wild-type tester had to be replica plated onto minimal agar to check for auxotrophic recombinants since the red pigment marker (*ade6-704*) was absent in both strains of such crosses.

Fig. 3 Isolation of haplo-vital *sup12-UGA* strains by the generation of a *sup3-UCG* allele. The crosses involved and the strains used are identified with letters *a–h*. The ploidy of the strains is indicated by *n* (haploid) and 2*n* (diploid). For *f*, *g* and *h* crosses with the reciprocal mating-type configuration were also performed, depending on the nature of the isolate to be tested. For further explanations see text.

mental selfings was due to an active suppressor allelic with the doubly-marked input allele in the vast majority of cases (that is, *sup3-UGA,rX* strains produced predominantly *sup3-UGA* revertants and *sup9-UGA,rX* strains produced mostly *sup9-UGA* prototrophs). This contrasts with the controls which gave back mutations at the *ade* loci and forward mutations at the suppressor loci with varying but comparable frequencies. The revertants designated 'others' in Table 1 have not been analysed further. They might comprise weak omnipotent suppressors or allosuppressors[25].

On the basis of mutation alone one would have to postulate that the inactivating *r* sites would have an unusually high probability of being changed back to the original wild-type state, thus restoring suppressor activity. This explanation is very unlikely. We therefore rather assume that recombination is responsible for the observed phenomenon. As identical alleles of the marked suppressor gene are involved in selfings, no recombinants are expected to occur following their interaction. We postulate that non-allelic but related wild-type genes (that is, other $\mathrm{tRNA}^{\mathrm{Ser}}$ genes) interact with the doubly marked gene. According to this interpretation, gene segments carrying the inactivating *r* sites but not the anticodon sequence are replaced by the corresponding sequences of the wild-type partners in a unidirectional process of gene conversion[14].

Besides the observed import of information into the marked suppressor gene, export of the suppressor active anticodon sequence into related wild-type genes is also expected to occur. Prime candidates to act as acceptors are the *sup9*$^+$ gene in *sup3-UGA,rX* selfings and the *sup3*$^+$ gene in *sup9-UGA,rX* selfings. If such transfers occur non-reciprocally, however, the haploid progeny will be lethal because both $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCA}}$ genes will be of mutant constitution, thus depriving the cell of functional $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCA}}$ (for example, *sup3-UGA,rX sup9-UGA*)[20]. That no-*sup9-UGA* revertants are observed in selfings involving *sup3-UGA,rX* and vice versa is thus expected and rests on the special situation in *S. pombe* that *sup3*$^+$ and *sup9*$^+$ are the only two genes producing functional $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCA}}$. The experimental system has therefore to be modified so as to demonstrate export of suppressor active anticodon information into companion wild-type genes.

Export of information generates a novel haplo-lethal suppressor

To determine whether the postulated export of suppressor active anticodon information does occur, we analysed selfings of diploid strains. The results are given in the lower part of Table 1 (expts 13–15) and in Fig. 1. Our interpretation is outlined in Fig. 2. Again, as in the case of haploid strains, the reversion frequency was clearly elevated in selfings involving inactivated suppressor genes as compared with the control. The selfing involving the *sup3-UGA,r36* allele is particularly instructive. Not only did we find prototrophic diploids carrying active *sup3-UGA* alleles, but also strains carrying *sup9-UGA* or a new suppressor, *sup12-UGA*, in significant excess over the control (Fig. 1).

The *sup3-UGA* bearers are explained as in the case of haploid selfings. The increased occurrence of *sup9-UGA* events is taken as evidence for genetic export of the suppressor active anticodon sequence from *sup3-UGA,rX* to *sup9*$^+$, again via gene conversion. Note that in this case the two interacting partners are located on different chromosomes (Fig. 2). These strains can survive as diploids, in contrast to the haploid situation, because they harbour one unmutated $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCA}}$ gene (*sup9*$^+$).

Evidently, a second gene can accept suppressor active anticodon information by the same mechanism, namely *sup12*$^+$ (UCG). The original constitution of these revertants is depicted in Fig. 2*c*. On sporulation, each tetrad gave two lethal and two auxotrophic spores. Thus, *sup12-UGA* is a recessive lethal suppressor. That it is a suppressor in its own right and not an allosuppressor acting in conjunction with *sup3-UGA,rX* was demonstrated by replacing the doubly-marked *sup3* background (for example, *sup3-UGA,r36*) by a homozygous wild-type background (*sup3*$^+$). Such diploids of constitution h^+ *ade6-704 sup12-UGA*/h^- *ade6-704 sup12*$^+$ are still prototrophic and produce two lethal and two auxotrophic segregants per tetrad on sporulation. In addition, *sup12* does not show genetic linkage with either *sup3* or *sup9* (data not shown).

The *sup12* gene, which had not been identified genetically before, is identical with the $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCG}}$ gene whose sequence has been published[23] (see below). As *sup3*$^+$ and the $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCG}}$ gene differ only by two base pairs in their coding regions, it is likely that they can interact as discussed above. Because *sup12-UGA* is haplo-lethal, we conclude that no substitute exists for the product of the $\mathrm{tRNA}^{\mathrm{Ser}}_{\mathrm{UCG}}$ gene. In addition, it is interesting that the change of *sup12*$^+$ (UCG) to *sup12-UGA* requires 2 bp changes in the anticodon sequence. This should easily occur via gene conversion but only very rarely by spontaneous mutation.

Haplo-vital *sup12-UGA* strains can be derived by further intergenic exchanges

As genetic analysis with a haplo-lethal suppressor is tedious, we sought a way to change one of the genes coding for UCA reading tRNA to an allele producing a UCG reading tRNA. The procedure to obtain haplo-vital *sup12-UGA* isolates is outlined in Fig. 3. The experiment was started with one of the original *sup12-UGA* diploids derived from selfing 15 (Table 1) and is depicted in Fig. 3*a*. A derivative of (*a*) homozygous for one of the mating-type alleles was crossed to an *ade6-704/ade6-704* diploid homozygous for the opposite mating-type allele. From this cross segregant (*b*) was obtained. On sporulation, vital progeny were dark red exclusively (*ade6-704 sup3*$^+$), in contrast to the meiotic progeny of (*a*) which are all pink, the particular *sup3* allele involved being responsible for this colour difference (*ade6-704 sup3-UGA,r36*). The vast majority of haploid spores from (*b*) will not grow on minimal agar: 50% are lethal due to *sup12-UGA*, 50% are adenine dependent. Nevertheless, two types of haploid prototrophs might rarely occur via mutation or information transfer: (1)

Active suppressors at the *sup3* or *sup9* locus, if they inherit at the same time *sup12*$^+$. They are normal suppressors and will not generate lethal progeny in crosses with standard partner strains. (2) Strains with a mutant anticodon information at *sup3* or *sup9* resulting in the production of $tRNA^{Ser}_{UCG}$ rather than $tRNA^{Ser}_{UCA}$ (for example, strain *c*, Fig. 3). If they carry *sup12-UGA* at the same time, such strains are haplo-vital prototrophs; lethality resulting from mutation of the only naturally occurring $tRNA^{Ser}_{UCG}$ producer (*sup12*) has now been by-passed. For instance, *sup3-UCG* will produce $tRNA^{Ser}_{UCG}$, *sup9*$^+$ will form $tRNA^{Ser}_{UCA}$ and *sup12-UGA* suppressor-active $tRNA^{Ser}_{UGA}$. In crosses with standard partners, lethal progeny are expected to be produced due to the separation of *sup3-UCG* from *sup12-UGA*.

Among ~3×10^7 spores of strain (*b*), 11 haplo-vital prototrophs were obtained. Ten of them did not segregate lethal progeny in crosses with a standard partner and were discarded. The remaining one of presumed constitution (*c*) was crossed to *h*$^+$ *ade6-704* (*d*). The following tetrads were observed: 9 parental ditypes (2 red and 2 white colonies per tetrad), 17 tetratypes (2 red, 1 white, 1 lethal) and 5 non-parental ditypes (2 red and 2 lethal). The same strain (*c*) was also crossed to *h*$^+$ *ade6-704 sup3-UGA* and *h*$^+$ *ade6-704 sup9-UGA*. These crosses gave results compatible with two and three independent factors segregating, respectively, thus indicating that the derived strain carries a *sup3-UCG* rather than a *sup9-UCG* allele, as shown in (*c*). Physical evidence that the *sup3-UCG* allele originated from intergenic conversion and not from mutation is given below.

Red strains from non-parental ditype tetrads of cross (*d*) should be of constitution (*e*). Although phenotypically not distinguishable from normal red *ade6-704* strains, they are predicted to carry the mutant *sup3* allele *sup3-UCG*. This 'helper' strain was crossed to mating-type homozygous derivatives of all 22 *sup12-UGA* diploids obtained from selfing 15 (Table 1). These triploid crosses are shown diagrammatically in (*f*) and (*g*). Some of the diploid parents used carried the original *sup3-UGA,r36* background (*g*), others the *sup3*$^+$ background (*f*). In all cases haploid prototrophic recombinants were easily obtained. In contrast, this did not occur if a normal *ade6-704 sup3*$^+$ strain was the haploid parent in such triploid crosses. All these haploid prototrophs were involved in crosses with each other (cross type (*h*)). In all cases the vast majority of progeny colonies was white. This indicates that the determinants responsible for prototrophy in the original diploids are indeed allelic (*sup12-UGA*).

Having obtained haplo-vital *sup12-UGA* strains, we proceeded to determine the chromosomal location of this suppressor (data not shown). Based on the analysis of 94 tetrads of a cross homozygous for *ade6-704* and *sup3-UCG* and heterozygous for *ura1*, *pro1* and *sup12-UGA*, we inferred the arrangement *ura1*–23 centimorgans–*pro1*–9cM–*sup12* on chromosome I[26].

Physical evidence for intergenic conversion

By restriction analysis of DNA from the relevant strains and by filter hybridization experiments according to Southern[27] we obtained evidence for the identity of the *sup12-UGA* suppressor allele with the known $tRNA^{Ser}_{UCG}$ gene. The data also ndicate that non-adjacent base pairs have been substituted in *sup3-UCG* in comparison with *sup3*$^+$ (Fig. 4). In addition, *sup3-UCG* has been sequenced (Fig. 5).

Genomic blots give complex hybridization patterns, because one is dealing with a family of cross-hybridizing genes. In addition to the well characterized *sup3*, *sup9* and *sup12* genes there is a further related sequence present in the genome (data not shown). Figure 4*a* gives a simplified restriction map of the chromosomal region with the $tRNA^{Ser}_{UCG}$ gene and the sequence of its non-coding strand comprising the anticodon and the 5′ part of the intron[23]. The sequence of the corresponding region of *sup3-UGA* is also given[21].

The phenotypic effect of *sup12-UGA* concerning suppression is identical with that of the other opal suppressors inserting serine (*sup3-UGA*) or leucine (*sup8-UGA*) which are known to code for suppressor tRNAs with the anticodon U*CA[28,29]. Thus, *sup12-UGA* most probably carries the anticodon sequence TCA which abolishes the two restriction sites present at this location in *sup12*$^+$ (Fig. 4*a*). In fact, a new and longer *Eco*RI restriction fragment is found in DNA of *sup12-UGA*/*sup12*$^+$ diploids. In the haplo-vital *sup3-UCG sup12-*

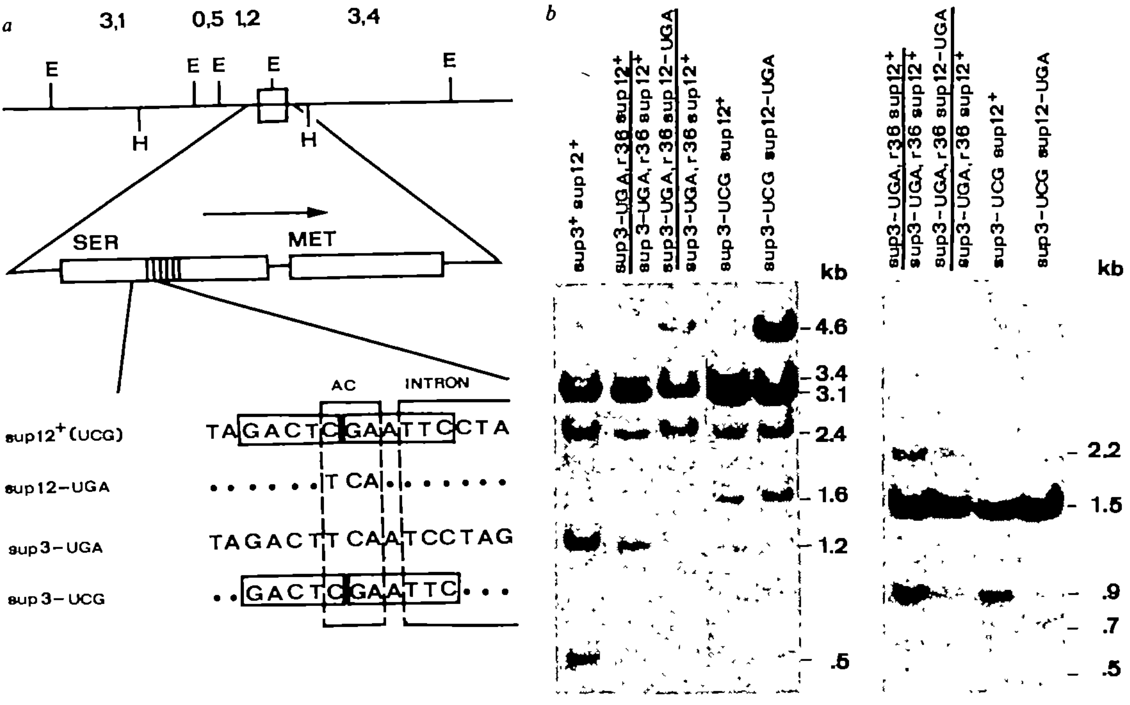

Fig. 4 Physical evidence for intergenic conversion. *a*. The chromosomal organization of the *sup12* locus and the relevant sequences of the anticodon regions of *sup12*$^+$ and *sup3-UGA* are represented[21,23] The *Eco*RI restriction sites (E) and the size of the resulting fragments in kilobases are indicated. The two *Hin*dIII sites (H) delimit the cloned fragment present in the chimaeric plasmid pYM118 that carries the $tRNA^{Ser}_{UCO}$–$tRNA^{Met}_{i}$ genes[23]. In the blow up the tRNA genes are shown as boxes. The shaded area signifies the intron and the arrow the direction of transcription Below, excerpts of the published sequences of *sup12*$^+$ (ref. 23) and *sup3-UGA*[21] are given as well as the deduced sequences of the two intergenic convertants analysed. The anticodons (AC) and the 5′ border of the introns are marked with broken lines The relevant restriction sites recognized by the *Eco*RI (GAATTC) and *Hin*fI (GANTC) endonucleases are boxed. *b*, On the left hybridization patterns according to Southern[27] are shown that were obtained after digestion of genomic DNA with *Eco*RI. The corresponding results obtained with *Hin*fI digests are given on the right. The hybridization probe consisted in the nick-translated *Hin*dIII fragment from the recombinant plasmid pYM118[23]. Above each lane the genotype of the haploid or diploid strain is given that served as source of the DNA The novel *Eco*RI fragment of 4.6 kb length is present in strains carrying *sup12-UGA*, while the new fragment of 1.6 kb length correlates with *sup3-UCG*. In strains with the *sup3-UCG* allele the 2.2 kb *Hin*fI fragment is missing and a new 0.7 kb fragment appears. For more details see the text.

Fig. 5 Nucleotide sequence of the intergenic convertant *sup3-UCG*. The noncoding strands of the tRNA genes *sup3⁺* (small letters) and *sup12⁺* (capitals) and their flanking sequences were taken from refs 21 and 23. Between them the sequence of *sup3-UCG* is given. It differs from *sup3⁺* at all of the eight positions (capitals) that vary between *sup3⁺* and *sup12⁺* (asterisks). Thus, the conversion event includes a block of at least 33 nucleotides. No change was observed between *sup3-UCG* and *sup3⁺* in the 3′-flanking region for the first 40 nucleotides downstream of the tRNA$_1^{Met}$ gene. In the 5′-flanking region at least the primer oligonucleotide sequence must be conserved. DNA from a strain carrying *sup3-UCG* was digested with *Hin*dIII and ligated into the plasmid pTR262 (ref. 32) which allows positive selection for chimaeric plasmids. Plasmids harbouring *sup3-UCG* were identified by colony hybridization with a nick-translated probe carrying the *sup3-UGA* gene. Subsequently, a *Hin*dIII–*Bam*HI fragment of 950 bp carrying the *sup3-UCG* gene was transferred from the chimaeric plasmid to the phage M13mp8 (ref. 33). Single-stranded phage DNA served as template for nucleotide sequencing according to the dideoxy termination method[34] using as primer a synthetic tetradecamer; its nucleotide sequence is boxed. The primer (Applied Biosystems) was a gift of Dr D Söll. Detailed cloning and sequencing procedures will be described elsewhere.

UGA strain the new 4.6-kb fragment is still visible, while its two constituting subfragments of 3.4 and 1.2 kb length (as present in *sup12⁺* DNA) are missing (Fig. 4*b*). Surprisingly, no longer fragment appears in the corresponding *Hin*fI digests. When the sequences in the more distal parts of the introns of *sup12⁺* and *sup3-UGA* (Fig. 5) are examined, one discovers that there is the potential for the creation of a new *Hin*fI site in *sup12-UGA* by conversion. This explanation for the lack of a larger *Hin*fI fragment in *sup12-UGA* strains has to be tested by nucleotide sequencing.

The *sup3-UCG* convertant (presumed anticodon CGA) was derived from *sup3⁺* (anticodon TGA) as described above. But it has been shown that *sup3-UCG* convertants can also be obtained starting with *sup3-UGA* alleles (R. Aebi, C. Gysler & W. Heyer, personal communication). A new *Eco*RI site should be created in the *sup3-UCG* allele only if the convertant received its anticodon sequence from *sup12⁺* (anticodon CGA) together with at least part of the intron of *sup12⁺* (see Fig. 4*a*). In fact, the strains carrying the *sup3-UCG* allele yield a new shorter *Eco*RI fragment of 1.6 kb length (Fig. 4*b*). If a homologous *sup3* hybridization probe is used instead of the heterologous *sup12* probe an additional new fragment of 0.8 kb appears (data not shown). A band corresponding to the original *sup3* fragment of 2.4 kb (1.6 + 0.8 kb) is always visible, because it coincides with an *Eco*RI fragment from one of the other cross-hybridizing genes. Finally, the presence of the *Hin*fI site in the *sup3-UCG* allele (in contrast to *sup3-UGA*) is documented by the disappearance of the 2.2 kb *Hin*fI fragment in DNA from *sup3-UCG* strains (Fig. 4*b*). Instead, a new fragment of 0.7 kb length hybridizes to the probe, whereas the other subfragment of 1.5 kb length coincides with a fragment that stems from the *sup12* gene.

Our interpretation of these and further data not shown here is that multiple and nonadjacent base-pair changes occurred during the creation of the particular *sup12-UGA* and *sup3-UCG* alleles. This is best explained by intergenic conversion. To confirm this interpretation we are now cloning and sequencing the relevant genes. Very recent nucleotide sequence data concerning *sup3-UCG* actually show that in this intergenic convertant the whole intron sequence (differing at six nonadjacent positions from the *sup3⁺* intron sequence) and the sequence coding for the loop of the extra arm (differing at one position from *sup3⁺*) have been transferred from *sup12* to *sup3* (Fig. 5).

Discussion

From the evaluation of selfings of auxotrophic nonsense mutants carrying inactivated suppressors we conclude that recombinational information transfer occurs between the three unlinked serine tRNA genes *sup3*, *sup12* (both on chromosome I) and *sup9* (chromosome III) in *S. pombe*. This interpretation, in contrast to mutation, is discussed in detail in an earlier publication[19]. The crucial points are: (1) Much more prototrophs are obtained in selfings of inactivated suppressors (frequency range: 1.4×10^{-7} to 20×10^{-7}) than in controls that measure the mutational background (0.3×10^{-7}, Table 1). (2) In selfings of haploids the large majority of prototrophs (> 90%) are due to import of wild-type information into the marked tRNA gene. The gene thereby loses the inactivating secondary lesion and becomes suppressor active again. Only a minority of prototrophs (<10%, Table 1) are due to mutational events elsewhere in the genome. In selfings of diploid strains which permit to detect even recessive lethal events, we have now demonstrated in addition export of suppressor active anticodon information from the inactivated gene to other genes of the family. In this way a new opal suppressor has been obtained spontaneously that was never observed in controls (frequency: 1.7×10^{-7} in selfings of the inactivated allele *sup3-UGA,r36*). Restriction analysis and nucleotide sequencing has revealed multiple and nonadjacent base-pair changes in specific convertants.

The mechanisms responsible for information transfer between unlinked genes may be identical or related to the ones that operate in homologous recombination between alleles[14]. If this is true, it follows from the present results that blocks of conserved sequences as short as 200 bp embedded in unrelated sequences are sufficient for the initiation of hybrid-DNA formation, which with or without subsequent mismatch repair can result in gene conversion. This interaction may take place between short conserved sequences in the lateral DNA loops of different chromosomes.

Recently it has been shown *in vitro* that *recA* protein from *E. coli* is unable to extend hybrid-DNA formation through regions of DNA with an average of 1 mismatch per 10 bp[30]. Our own results show that eight mismatches within a stretch of 20 bp are no obstacle to exchanges between *sup3* and *sup12 in vivo*. It is true that suppressor anticodon export from *sup3-UGA,rX* to *sup12⁺* is only half as frequent as export to *sup9⁺* that carries an intron identical to *sup3* (Fig. 1). But there may be alternative explanations for this discrepancy, for example, effects due to the specific chromosomal location of the genes involved.

If events of intergenic conversion were frequently associated with crossing-over as in inter-allelic gene conversion, various chromosomal rearrangements would result and many such events would be lethal. In a first search no chromosomal rearrangements were identified among intergenic convertants (C. Gysler, personal communication). However, more has to be known about the orientation of the three tRNA genes with respect to their centromeres before the potential for the creation of viable rearrangements can be assessed.

More light may be shed on the mechanisms of intergenic conversion by studying other tRNA gene families. Experiments with suppressors derived from two leucine tRNA genes (not shown) indicate that they participate less frequently in intergenic conversion events. This may be due to shorter blocks of near-identical sequence in this gene family, since as a rule tRNA genes are not arranged in multimers in eukaryotes. This results in blocks of conserved sequence of not more than 100 bp.

Like inter-allelic recombination, intergenic conversion also seems to be influenced by specific marker effects. In the serine tRNA genes certain second-site mutations display vastly enhanced recombination frequencies in inter-allelic recombination[24]. The one such second-site mutant tested, *sup3-UGA,r10*, gives also the highest frequency of intergenic conversion (Table 1).

It has been shown experimentally that intergenic conversion occurs in various other systems[15–18] (see introduction). One additional example of *in vivo* formation of a 'hybrid' tRNA gene derived from two different tRNA genes has been discovered in the bacteriophage T4 (ref. 31 and W. McClain, personal communication). Intergenic conversion is likely to be the main mechanism responsible for concerted evolution of families of dispersed genes and also of linked genes[6,7,16,17]. It may propagate or eliminate specific mutations within a gene family and in this way contribute to conservative evolution and rapid sequence change. A recent review on the evolution of tRNA sequences includes a thorough discussion of the problems encountered in the construction of phylogenetic trees based on sequence comparisons[31]. Here we stress that the occurrence of intergenic conversion violates one of the fundamental assumptions used in the construction of phylogenetic trees, namely that the daughter copies will not exchange sequences after a gene has been duplicated.

The described selection of serine tRNA gene variants which are altered in intron sequences but remain functional at the tRNA level will prove useful for an understanding of tRNA biosynthesis (removal of intron sequences). From sequence data on inactive tRNA gene variants which carry secondary lesions introduced by either mutation or intergenic conversion one will also learn more about tRNA function.

We thank Dr D. Söll and his collaborators for the communication of unpublished results, for sending the recombinant plasmid pYM118 and for introducing H.A. to DNA sequencing methods. Also acknowledged is the help of Wolf-Dietrich Heyer in the cloning and sequencing project. This work was supported by the Swiss NSF.

DNA-mediated gene transfer was used to identify cloned class I genes from the major histocompatibility complex of the BALB/c mouse. Three genes encoding the transplantation antigens H-2 K^d, D^d and L^d were identified as well as genes encoding the Qa-2,3 and two TL differentiation antigens. As many as 10 putative novel class I genes were detected by the association of their gene products with β_2-microglobulin. Alloantiserum prepared to one of the novel antigens was used to demonstrate the expression of the previously undetected antigen on spleen cells of various inbred, congeneic, and recombinant congeneic strains of mice.

THE major histocompatibility complex of the mouse encodes a family of cell-surface antigens known as the class I molecules. These gene products, which fall into two categories, are encoded by distinct regions of the major histocompatibility complex. The H-2 region encodes the transplantation antigens which were initially defined by allograft rejection[1,2]. These antigens are expressed on most somatic cells of the mouse and are involved in the T-cell recognition of cells altered by viral or neoplastic transformation (for a review see refs 3, 4). The second category of class I antigens are the haematopoietic differentiation antigens encoded by genes in the Tla region. The Tla region encodes three distinct types of differentiation antigens, Qa-1, Qa-2,3 and TL[5]. The TL antigens are expressed only on certain subpopulations of thymocytes and their

Table 1 Summary of the coding assignments for the class I genomic clones

Clone	Reaction of transformants with antibodies specific for K^d	D^d	L^d	Qa-2,3	TL^c	Assignment
λ1.3	+					K^d
λ26.1	+					K^d
λ21.1	+					K^d
c17.1	+					K^d
c18.1		+				D^d
λ27.5			+			L^d
c59.2			+			L^d
c50.2				+		Qa-2,3
λ17.3					+	TL
c6.3					+	TL
λ24.8					+	TL
66.1					+	TL

Mouse L tk⁻ cells were co-transformed with ~1 μg of DNA from each of the λ and cosmid clones (see text) and the HSV tk gene in pBR322 (ptk5) as previously described[18]. For those cosmid clones containing more than one gene, the clone DNA was digested with an appropriate restriction enzyme to inactivate all but a single gene for transformation (see ref. 24). Uncloned tk^+ transformants selected in hypoxanthine/aminopterin/thymidine medium[38] were panel analysed by radioimmunoassay as previously described[18] using monoclonal hybridoma antibodies 34-1-2 to K^d (ref. 39), 34-2-12 to D^d (ref. 39), 30-5-7 to L^d (ref. 40), D3.262 to Qa-2,3 (ref. 41) and TLm(i) to TL[33]. Positives are indicated for those transformants which yielded at least 5,000 c.p.m. of iodinated (^{125}I) protein A bound (see Figs 2, 4) with a 10^{-2} or 10^{-3} dilution of the ascites fluid in duplicate transformation experiments. Background for the various antibodies and transformants ranged over 100 to 300 c.p.m., except for the IgM Qa antibodies which utilized a facilitating reagent (see Fig. 4). The active genes on cosmid clone 17.1, 18.1, 59.2, 50.2, 6.3 and 66.2 are the first gene on cluster 11, the first gene on cluster 13, the second gene on cluster 2, the second gene on cluster 6, the second gene on cluster 4, and the first gene on cluster 5, respectively (see Fig. 5).

neoplastic counterparts in certain T-cell leukaemias[6]. The Qa-1 antigen is expressed by thymocytes, peripheral T and B cells, as well as lymphoblasts[7]. The Qa-2,3 antigens are found on a subset of bone marrow-derived cells[8]. The biological functions of the TL or Qa antigens are not known.

Class I antigens have been characterized using specific alloantisera and monoclonal antibodies prepared by the appropriate cross-immunizations with cells from inbred, congeneic and recombinant strains of mice. Serological analysis has demonstrated that the transplantation antigens are extremely polymorphic and that different strains of mice have distinct combinations or haplotypes of class I alleles. Particular class I molecules are denoted by appropriate letters with a superscript small letter for the haplotype. For example, the serologically defined transplantation antigens of the BALB/c mouse which is of the $H\text{-}2^d$ haplotype are denoted K^d, D^d, L^d or R^d.

Class I molecules of both categories appear to share a common structure. The class I polypeptide is a 45,000-molecular weight integral membrane protein which is noncovalently associated with a 12,000-molecular weight polypeptide, β_2-microglobulin. Class I molecules consist of three external domains, each of ~90 amino acids, a transmembrane region of ~40 residues, and one cytoplasmic domain of 30 residues[9,10].

Class I cDNA clones have been characterized and used as probes to obtain genomic clones containing class I genes[11–17]. Two genes isolated from a BALB/c Crgl sperm DNA library constructed with the lambda bacteriophage (λ) vector have been extensively characterized. The class I gene from clone λ27.1 is a pseudogene which has been mapped to the Qa-2,3 subregion of the Tla region by restriction enzyme site polymorphisms[15]. DNA sequence analysis of gene 27.1 shows that this class I gene is divided into eight distinct exons encoding each of the individual domains of a class I molecule. Recently, DNA-mediated gene transfer and radioimmunoassays were used to demonstrate that a gene from clone λ27.5 encodes the $H\text{-}2L^d$ transplantation molecule[18]. The L^d molecules produced by mouse L cells transformed with λ27.5 DNA were shown to be virtually indistinguishable from the L^d molecules expressed on spleen cells from BALB/c mice by biochemical, immunological and functional criteria[18–21]. The DNA sequence of gene 27.5 is identical to that of the L^d antigen at all 77 positions that can be compared[22]. Other laboratories have also used gene transfer to identify the cloned class I genes from libraries constructed from tissues or tumour cell lines from other substrains[17] and strains[23] of mice.

In an attempt to assess the total number of class I genes contained in the BALB/c mouse, genomic clones containing class I genes have been isolated from a cosmid library constructed from BALB/c sperm DNA[24]. Fifty-four cosmid clones containing 36 unique class I genes have been assigned to 13 distinct groups or clusters encompassing 837 kilobases of DNA. These include most of the class I genes in the BALB/c mouse.

Here, we have used gene transfer and serological analyses to examine individual class I genomic clones from the λ and cosmid libraries. Cloned class I genes encoding the serologically defined H-2 K^d, D^d, L^d, Qa-2,3 and TL antigens have been identified. Evidence is also presented for as many as 10 additional novel class I genes encoding products not previously defined serologically.

Analysis of 96 λ and 36 cosmid class I clones by gene transfer

In an attempt to examine most class I genes from the BALB/c mouse, 96 genomic clones isolated from the λ library and 36 genomic clones previously isolated from the cosmid library (designated c) were analysed. DNA from each of these genomic clones, together with the herpes viral thymidine kinase gene, was used to co-transform thymidine kinase-negative (tk⁻) mouse L cells as previously described[18]. The class I $H\text{-}2^d$

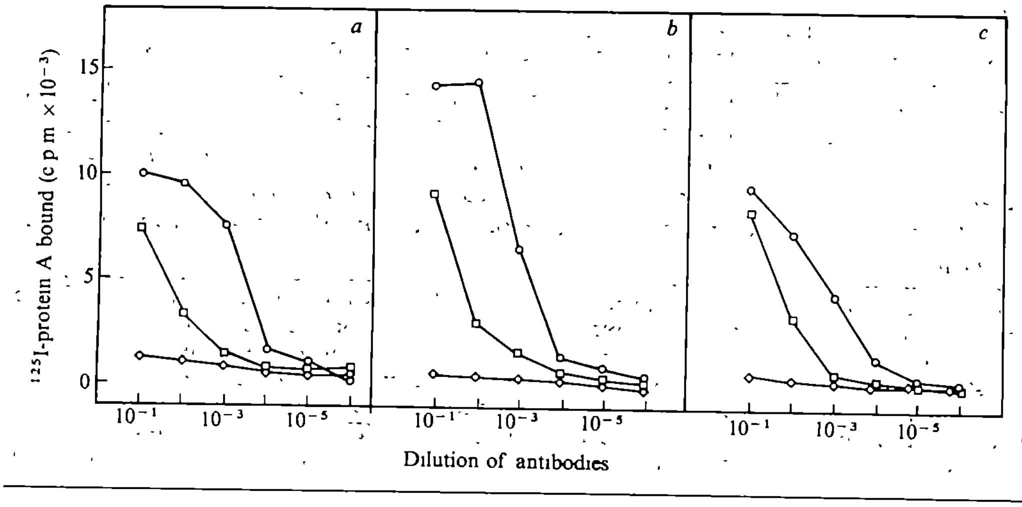

Fig. 1 Radioimmunoassay of λ1.3, λ21.1 and λ26.1 transformants. Transformants which reacted in the panel analysis (Table 1) with antibodies 34-1-2 to K^d molecules were tested by the cell-binding radioimmunoassay with: ○, 34-1-2 antibodies to K^d; □, 20-8-4 antibodies to K^b [42] which react with K^d molecules; and ◇, 34-2-12 antibodies to D^d. Transformants derived from transfection with DNA from clones λ26.1 (*a*), λ21.1 (*b*) and λ1.3 (*c*). Spleen and Ltk^+ controls are shown in Fig. 4.

products of the transformed L cells were detected by radioimmunoassay and analysed by two-dimensional gel electrophoresis. Since mouse L cells are fibroblasts derived from C3H mice of the *H–2*^{k} haplotype, the endogenous K^k and D^k transplantation antigens can readily be distinguished from any of the BALB/c class I molecules of the *H–2*^{d} haplotype by appropriate monoclonal antibodies. The mouse L-cell fibroblasts do not express the differentiation antigens Qa-1, Qa-2,3 or TL. These results are summarized in Table 1. In almost all cases, the binding of specific antibodies to the transformants was comparable to that of the binding of the antibodies to the corresponding antigens and not cross-reacting antigens (see Fig. 4).

Identification of genes encoding the H–2 K, D and L transplantation antigens

The L-cell transformants derived from transfections with the λ1.3, λ26.1 and λ21.1 clones express K^d molecules which are virtually indistinguishable in their patterns of serological reactivity with two different monoclonal antibodies to the K^d molecule (Fig. 1), both of which react as strongly with these transformants as they do with spleen cells (see Fig. 4). No reactivity is observed with these four transformants using monoclonal antibodies specific for D^d or L^d antigens (see Fig. 1 legend). Antibodies specific for the K^d molecule do not react with mouse L cells transformed only with the thymidine kinase gene (see Fig. 4). These are designated tk^+ transformants. To determine whether these three class I genes encode distinct gene products, the antigens were isolated by immunoprecipitation and analysed by two-dimensional gel electrophoresis (Fig. 2). As the class I antigens of different haplotypes each have distinct constellations of spots[25], we believe this approach is very discriminating. The products of class I genes 1.3, 26.1 and 21.1 appear extremely similar to one another and to the K^d molecules isolated from normal BALB/c spleen lymphocytes. However, minor electrophoretic differences were observed in the faint, lower molecular weight species (Fig. 2*a* and 2*e*).

As the electrophoretic patterns between products obtained from duplicate transformations appear identical, the variation in the lower molecular weight products may reflect differences in post-translational modifications of these molecules or differential alternative splicing, as has been previously suggested for class I genes[15]. Restriction map analyses of clones λ1.3, λ26.1 and λ21.1 (Fig. 3), however, suggest that the K^d genes they contain are identical to one another and also to the first gene on cluster 11 or clone c17.1 (see Fig. 5) which contains a K^d gene by transformation (Table 1, Fig. 4*a*). Thus, all of these clones appear to encode very similar or identical genes on an independently derived series of what we believe are overlapping clones, although we cannot exclude the possibility that certain of these genes may actually be distinct and yet appear identical by the limited restriction mapping we have carried out to date. These genes are currently being sequenced in order to resolve this issue.

Cosmid clone 18.1 contains an H–2D^d gene as demonstrated by the radioimmunoassay of the c18.1 transformants with monoclonal antibodies to theD^d antigen (Table 1, Fig. 4*b*). The 18.1 transformants reacted with antibodies specific for D^d products and not reagents which detect K^d, L^d, TL or Qa antigens. The D^d molecules expressed by the transformants are currently being compared with the molecules isolated from spleen cells by two-dimensional gels and tryptic peptide map analysis to confirm this identification. No lambda clones containing an H–2 D^d gene were identified (see below).

An H–2L^d gene has been identified on cosmid clone 59.2 by transformation (Table 1) and comparison of restriction maps between the c59.2 and λ27.5 genes[24]. The L^d molecules expressed on the corresponding transformants appear indistinguishable in radioimmunoassays from the products of the previously identified gene contained in clone λ27.5 (Fig. 4*c*).

The analyses based on 132 independent transformations resulted in the identification of at least one H–2K^d, a single H–2D^d and one H–2L^d gene. Serological evidence suggests that in some mice there may be multiple K and D gene products[26–31], and additional transplantation antigens such as R^d (ref. 32).

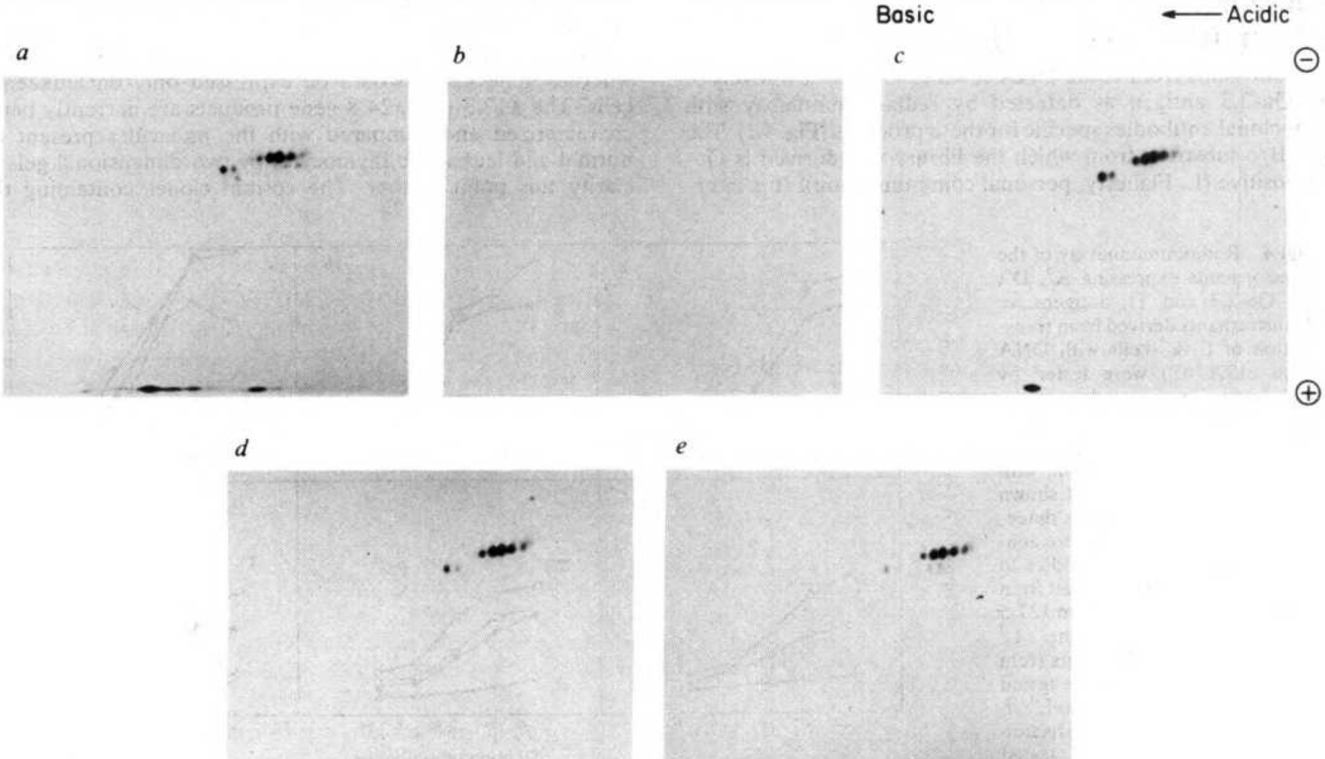

Fig. 2 Fluorographs of two-dimensional gels of H–2K^d molecules immunoprecipitated from cell lysates of BALB/cJ spleen lymphocytes (*a*), tk^+ cells transformed only with the tk gene (*b*), λ1.3 (*c*), λ26.1 (*d*) and λ21.1 (*e*) transformants. Cells were biosynthetically radiolabelled, immunoprecipitated with 20-8-4 monoclonal antibodies (supernatant fluids), and analysed by two-dimensional gel electrophoresis as previously described[18]. The gels were prepared for fluorography, dried and exposed for ~7 days.

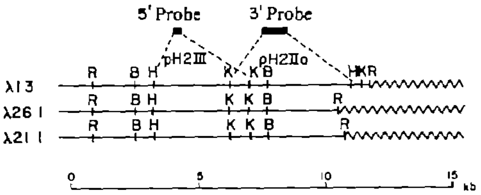

Fig. 3 Restriction maps of the lambda clones containing the K^d genes. DNA from each of the λ clones which yielded K^d-positive transformants was restriction-mapped with the indicated enzymes by single and double digestion as previously described[24]. The 5' probe pH-2III and the 3' probe pH-2IIa[11] were used to detect fragments containing coding sequences homologous to the class I genes (dashed lines). The pH-2III probe contains the sequences encoding amino acids 63–160 of a transplantation antigen and pH-2IIa amino acids 167–352. The coding sequences were orientated using sequencing subclones as previously described[22]. The solid line indicates the insert DNA, and the λ vector DNA is designated by the wavy lines. R, *Eco*RI; B, *Bam*HI; H, *Hin*dIII; K, *Kpn*I. The 3' *Eco*RI sites mark the linkers used in constructing the library.

The failure to find multiple class I K^d and D^d genes may be explained in several ways. First, the serological multiplicity of K or D antigens may arise from post-translational modifications or alternative patterns of RNA splicing. Second, different inbred strains may have different numbers of K and D genes. Third, multiple class I genes might appear identical by restriction mapping and still differ in their DNA sequences. In this case, multiple distinct genes might be confused with a single gene present on overlapping clones. Finally, these genes may not have been detected for various technical reasons, for example, failure to clone the gene or express the gene at levels detectable in the radioimmunoassay. For example, the radioimmunoassay is less effective with heterogeneous alloantisera and specific monoclonal reagents for the R^d or the Qa-1 gene products are lacking.

Fibroblast expression of gene encoding the mouse haematopoietic differentiation antigen Qa-2,3

Transformants from c50.2 DNA seem to express low levels of the Qa-2,3 antigen as detected by radioimmunoassay with monoclonal antibodies specific for these products (Fig. 4*d*). The BALB/c substrain from which the library was derived is Qa-2,3-positive (L. Flaherty, personal communication). It is interesting that *Qa-2,3*, a gene normally expressed only in haematopoietic cells, appears to be expressed in transformed fibroblasts. The fact that the Qa-2,3 differentiation antigen is expressed at low levels on haematopoietic cells[8] may explain why limited numbers of Qa-2,3 molecules are expressed in the transformed mouse L cells. It is difficult to ascertain the basis for the low level of expression of this antigen by the transformants. Several possibilities are now being investigated. For example, only rare transformants may have incorporated sufficient copies of the gene to override differentiation signals. In addition, glycosylation of the polypeptide in fibroblasts might, in this particular instance, alter the antigenicity of the molecule causing a less avid reaction with the antibodies. The fact that the c50.2 transformants exhibit elevated levels of β_2-microglobulin (see below) does suggest that significant amounts of the antigen may be expressed in an altered form associated with β_2-microglobulin. Accordingly, it has been difficult to obtain sufficient Qa-2,3 antigen from spleen cells or transformed L cells for two-dimensional gel analysis. The identification of a Qa-2,3 gene should readily permit its characterization at the DNA level.

Two different class I genes encode two distinct TL T-cell differentiation antigens

The TL antigens are expressed only on thymocytes at a certain stage of differentiation. In some inbred strains of mice, distinct TL molecules are expressed on certain leukaemic cells of T-cell origin[6]. Two monoclonal antibodies can distinguish these TL antigens. Antibodies denoted TLm(i) recognize TL determinants present on both normal and leukaemic cells, whereas antibodies designated TLm(iii) react only with the TL determinants on normal thymocytes[33]. Figure 4*e*, *f* shows that transformants from λ clone 17.3 reacted with both monoclonal antibodies at levels comparable to those observed with BALB/c thymocytes (Fig. 4*e*, *f*), whereas transformants from λ clone 24.8 reacted only with monoclonal antibodies TLm(i). These observations suggest that there are at least two distinct genes, λ17.3 and λ24.8, which encode two TL antigens. From the serological analyses described above, gene λ17.3 may be expressed on normal BALB/c thymocytes and leukaemic cells whereas gene λ24.8 would be expressed only on leukaemic cells. The λ17.3 and λ24.8 gene products are currently being characterized and compared with the molecules present on normal and leukaemic thymocytes by two-dimensional gels to clarify this point further. The cosmid clones containing the

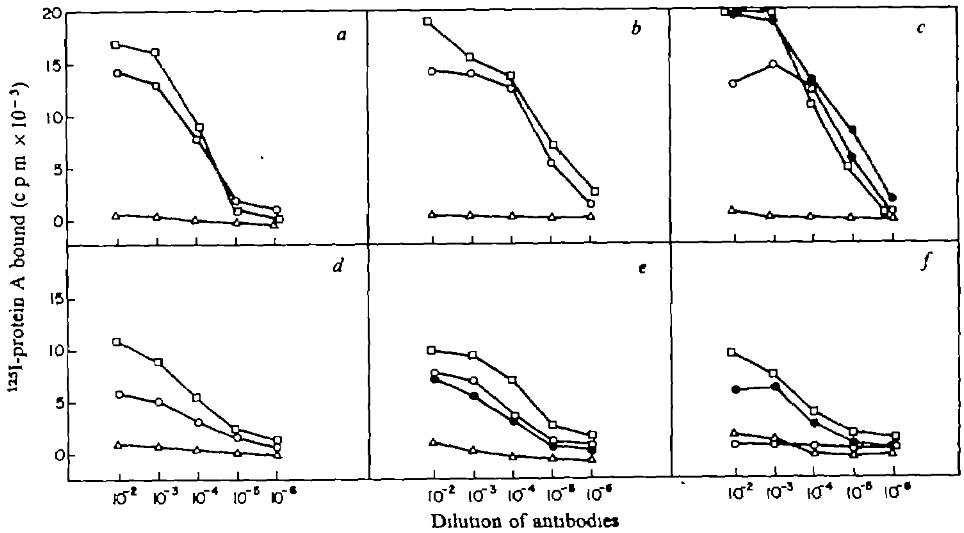

Fig. 4 Radioimmunoassay of the transformants expressing K^d, D^d, L^d, Qa-2,3 and TL antigens. *a*, Transformants derived from transfection of L tk$^-$ cells with DNA from c17.1 (○) were tested by radioimmunoassay for the expression of K^d molecules using 34-1-2 antibodies to K^d. *b*, Transformants from transfection with DNA from c18.1 (○) and shown to express D^d molecules as detected in the panel analysis were analysed using 34-2-12 antibodies to D^d. *c*, Transformants derived from transfection with DNA from λ27.5 (○), which contains the L^d gene[18,22], and transformants from DNA from c59.2 (●) were tested against 30-5-7 antibodies to L^d. *d*, Transformants from transfection with c50.2 DNA (○) were tested in a cell-binding radioimmunoassay using D3.262 monoclonal hybridoma IgM antibodies to Qa-2. Rabbit antiserum to mouse IgM (Bionetics) was used as a second step reagent before incubation of the cells with ^{125}I-protein A. *e*, Transformants derived from transfection with DNA from λ17.3 were tested against antibodies to TL (●) TLm(i) and (○) TLm(iii) (see text). *f*, Transformants from transfection with λ24.8 DNA were tested against the same antibodies to TL indicated in *e*. BALB/c spleen cells, panels *a*–*d* (□) or thymocytes, panels *e*–*f* (□) and Ltk$^+$ cells, panels *a*–*f* (△) were run as controls. Thymocytes and Ltk$^+$ cells in panel *e* were tested against TLm(i), panel *f* against TLm(iii).

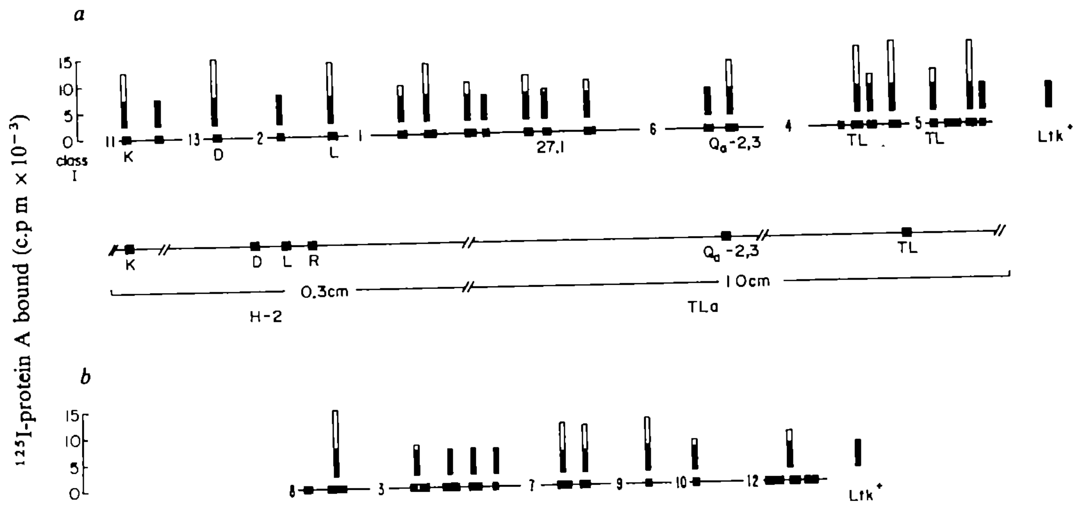

Fig. 5 Radioimmunoassay of cosmid transformants for β_2-microglobulin. The mixed population of tk$^+$ transformants derived from transfection with a single gene from each of the various cosmid clones, obtained by restriction digestion, was tested for the expression of β_2-microglobulin in a cell-binding radioimmunoassay using rabbit antiserum to rat β_2-microglobulin. Each transformant was assayed in duplicate against a 10^{-2} dilution of the antiserum. The numbers shown at the left indicate the c.p.m. of ^{125}I-protein A bound per 50,000 cells. Less than 10% variation in the number of c.p.m. was observed between duplicate transformations or assays. The dark portion of each bar represents the basal level of L-cell β_2-microglobulin measured for tk$^+$ transformants which is the average of duplicate samples tested (right). The open portion of each bar represents the total number of c.p.m. of ^{125}I-protein A bound for each transformant which exceeds the level on tk$^+$ cells. Cosmid clusters are represented schematically with the genes indicated as the enclosed boxes. Each cluster is comprised of a group of noncontiguous overlapping clones[24]. The cosmid cluster number is indicated to the left of the horizontal black line and the genes encoding the serologically defined products are indicated below the appropriate boxes. *a*, β_2-microglobulin on the surface of transformants derived from transfection with DNA from cosmid clones linked with mapped genes or genes encoding serologically defined antigens; *b*, undefined clusters only.

corresponding TL genes have been identified by transformation (Table 1, Fig. 5). The 17.3 TL gene appears to be the first gene on cosmid cluster 5 or clone 6.3, and the 24.8 gene the second gene on cosmid cluster 4 or clone 66.1. Since each TL gene maps to a separate cosmid cluster, they must be distinct genes. These results illustrate two important points regarding gene transfer into mouse L cells. First, as was noted for the Qa-2,3 gene, the TL genes which are developmentally regulated and expressed only on thymocytes can be expressed in fibroblasts as a result of transformation. Second, genes not expressed in the mouse except on leukaemias, such as gene λ24.8, can be expressed by transformed fibroblasts. It seems unlikely that the activation of endogenous L-cell genes encoding similar TL molecules would account for these results as restriction digestion of λ17.3 or λ24.8 DNA destroys the ability of these genes to transform L cells to the TL-positive phenotype.

Ten class I genes encode serologically undefined gene products

Of the 36 distinct class I clones, six contain genes encoding serologically defined gene products (Fig. 5*a*). The remaining class I genes are either pseudogenes or encode as yet unidentified cell-surface products. For example, they could encode nonpolymorphic molecules expressed on the surface of most cells which therefore would not have been detected by classical serological approaches. Alternatively, they might be differentiation antigens expressed at defined stages on tissues not yet tested for their ability to generate alloantisera. Cytoplasmic or secreted forms of class I molecules might represent another category of uncharacterized products.

We have used a simple but effective approach to identify class I gene products for which there are no specific serological reagents. All class I molecules studied associate with β_2-microglobulin before expression on the cell surface[34,35]. Therefore, the expression of foreign class I molecules on the surface of the mouse L cell should result in the elevation of the amount of β_2-microglobulin expressed on the cell surface. To test this hypothesis, a radioimmunoassay for cell-surface β_2-microglobulin was developed and used to quantitate the amount of β_2-microglobulin on several transformants expressing foreign serologically defined class I molecules as well as several which failed to react with any of the class I-specific antibodies. The tk$^+$ transformants express a basal level of β_2-microglobulin as do the mixed population of tk$^+$ transformants derived from transfection with the L^d gene cleaved into small coding fragments with *Bam*HI enzyme. In contrast, mouse L cells transformed with the L^d, D^d, K^d and TL genes all expressed levels of cell-surface β_2-microglobulin well above the background level as measured by radioimmunoassay (Fig. 5*a*). This increase is reproducible in that the measured levels of β_2-microglobulin obtained for duplicate assays or transformations vary by less than 10%. In addition, the elevation in β_2-microglobulin expression appears to be a stable phenotype, observed after 50 passages of some of the cell lines in culture. If elevated β_2-microglobulin expression results from the expression of additional class I molecules by the transformants, this phenotype would be stably expressed because it has been demonstrated

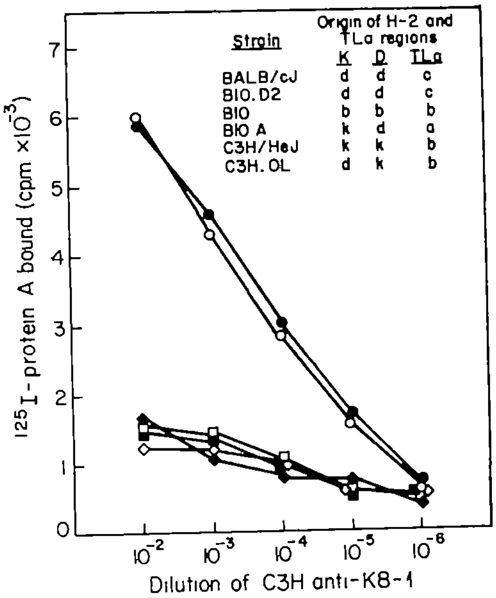

Fig. 6 Radioimmunoassay of spleen cells with C3H antibodies to K8-1 transformants. Four C3H mice were immunized by injecting 5×10^7 UV-irradiated K8-1 cells intraperitoneally every 2 weeks for 8 weeks. Mice were bled 7 days after the last injection and the antiserum used in the cell-binding radioimmunoassay against spleen cells as previously described[18]. Reaction of spleen cells from: ●, BALB/cJ; ○, B10.D2; ■, C3H/HeJ; □, C3H.OL; ◆, B10; ◇, B10.A. The origins of the H–2 and Tla regions for each of the mice are indicated in the panel.

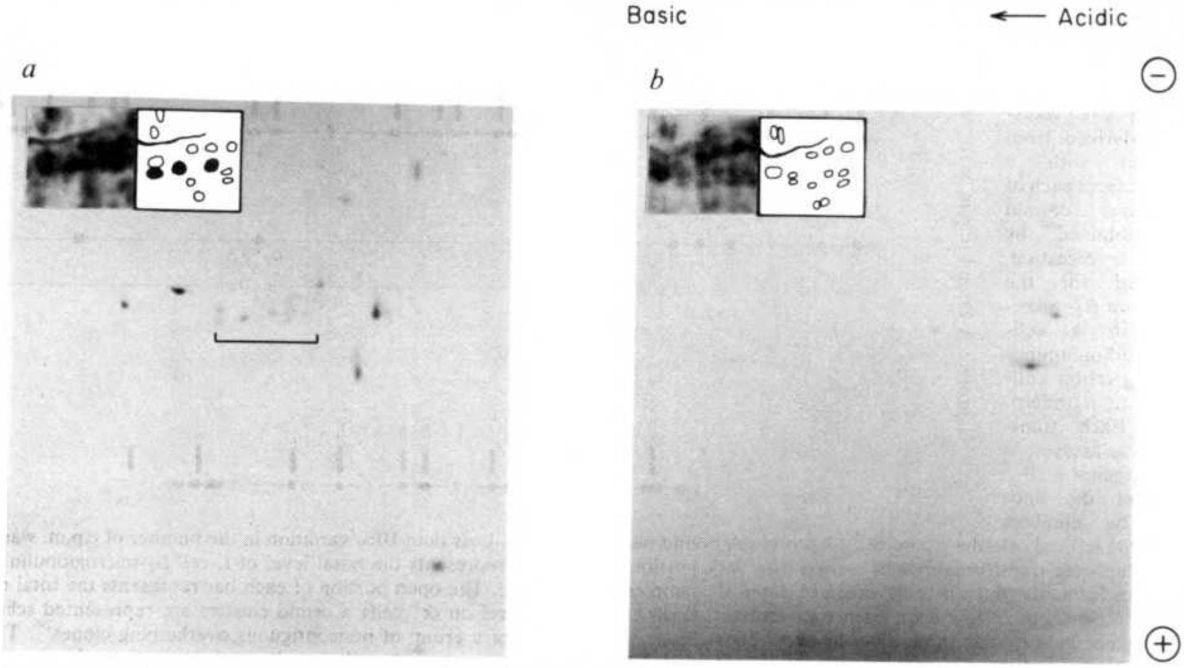

Fig. 7 Fluorographs of two-dimensional gels of the products of the c2.1 gene immunoprecipitated from K8-1 cells (*a*) and tk^+ transformants (*b*) using C3H antibodies to K8-1 transformants. The antibodies prepared in C3H mice against c2.1 transformants (K8-1 cells) were used to immunoprecipitate radiolabelled antigens for two-dimensional gel electrophoresis as previously described[18]. The insets contain longer exposures and diagrammatic representations of the 45,000-molecular weight region of each gel. Black spots represent the specific immunoprecipitated molecules from 8-1 cells.

previously that the expression of the transferred genes is a stable phenomenon[18].

The ability to measure an elevation in β_2-microglobulin expression by the pooled transformants is related to the fact that in the conditions used for transformation, nearly 100% of the co-transformants express significant and comparable levels of the foreign class I molecules[36]. It is important to stress that the twofold increase in the magnitude of the radioimmunoassay signal does not necessarily correspond with a twofold increase in the amount of β_2-microglobulin expressed (see ref. 36). These results suggest that the L cells possess the capacity to express additional class I molecules. It has recently been shown that the expression of foreign class I molecules does not occur at the expense of the endogenous $H\text{-}2^k$ products of the transformants[36]. Furthermore, we have observed significant levels of expression of as many as three different products by the triple K^d, D^d and L^d cloned transformant line, which demonstrates even greater than a twofold increase in the β_2-microglobulin radioimmunoassay signal.

At least 10 of the transformants which exhibited increased levels of β_2-microglobulin expression failed to react with any of the known serological reagents to class I molecules (Fig. 5*a*,*b*), suggesting that these cells produced novel products associated with β_2-microglobulin. Unfortunately, the heterologous antibodies to β_2-microglobulin proved relatively ineffective in precipitating class I molecules for two-dimensional gel analysis. Thus, we decided to prepare antisera directly against several of these gene products in order to demonstrate formally the presence of novel class I genes. Mouse L cells transformed with the $H\text{-}2L^d$ gene have been used to immunize C3H mice, the strain from which the L cell was derived, to generate alloantisera specific for the L^d molecule[20]. Similarly, C3H mice were immunized with L-cell transformants (K8-1) obtained by gene transfer with cosmid clone 2.1, the first gene on cosmid cluster 1 (see Fig. 5*a*). By radioimmunoassay, the antibodies specific for K8-1 cells reacted weakly with BALB/c spleen cells, whereas significantly lower reactivity was observed against BALB/c liver or thymus cells, and C3H spleen, liver or thymus cells (Fig. 6). Accordingly, these antibodies constitute an alloantiserum that was then used to screen spleen cells from a panel of different congeneic and recombinant congeneic strains of mice so that the location of gene c2.1 in the major histocompatibility complex could be assigned by preliminary mapping. These serological analyses suggest that gene c2.1 maps to the right of the complement region. More extensive mapping is required to pinpoint the location of this gene by serological analysis. Such analysis may be complicated if only certain strains of mice express the 2.1 gene products in a manner analogous to that of Qa or TL antigens. However, the data are consistent with the mapping of this gene by restriction enzyme polymorphisms, in that class I gene c2.1 is the first gene in the cosmid cluster containing gene 27.1, which had previously been mapped to the Tla region[15] (Fig. 5*a*).

The antiserum to the K8-1 cells immunoprecipitated molecules from K8-1 cells but not from tk^+ transformants or BALB/c spleen cells (Fig. 7). The products of the c2.1 gene appear to be ~45,000 molecular weight and to consist of a number of spots of the appropriate *p*I in a sequential array somewhat characteristic of class I molecules analysed on two-dimensional gels (see Fig. 2). β_2-Microglobulin could not be readily detected in 8-1 immunoprecipitates. This may be due to a low affinity between β_2-microglobulin and the 2.1 gene products, as has been described for certain $H\text{-}2^d$ molecules[37]. The origin of the additional products precipitated is unknown. The fact that these products cannot be isolated from spleen cells may be due to the fact that this antigen is expressed at low levels on lymphocytes. However, the ability to generate antibodies to the putative novel gene products expressed by the K8-1 transformants supports the existence of novel genes. Moreover, these genetic, serological and chemical data suggest that gene c2.1 encodes a class I molecule which may, because of its location within the major histocompatibility complex, be a differentiation antigen and not a ubiquitously expressed transplantation antigen.

Mapping of six serologically defined genes

The serologically defined class I genes have been localized within the major histocompatibility complex through the serological analysis of the highly polymorphic congeneic mouse strains. Thus the identification of these class I genes by DNA-mediated gene transfer allows us to map precisely the corresponding cosmid clusters into the major histocompatibility complex. It is interesting that only five class I genes shown in Fig. 5 map to the H–2 region (clusters 2, 11 and 13). Three class I genes encode defined transplantation antigens whereas the remaining two apparently do not encode detectable class I gene products. In contrast, 17 class I genes are contained in cosmid clusters which map to the Tla region. Four class I genes encode serologically defined differentiation antigens and eight encode novel gene products. One of the eight novel genes (c2.1) may encode a differentiation antigen based on the pattern of tissue distribution determined with the alloantibodies. Therefore, the Tla region contains far more class I genes than the H–2 region.

Cosmid clusters 3, 7, 8, 9, 10 and 12 do not express serologically defined gene products and, accordingly, cannot be mapped within the major histocompatibility complex (Fig. 5*b*). These six cosmid clusters contain 15 class I genes, six of which appear to express novel gene products. These clusters are now being mapped through the analysis of restriction enzyme site polymorphisms.

Conclusion

We have identified at least one H–2 K^d, D^d, L^d, possibly a Qa-2,3, and at least two TL genes from the BALB/c mouse. These genes have been mapped into 6 cosmid gene clusters containing 14 class I genes (Fig. 6), of which 9 lie in the Tla region and 5 in the H–2 region. As many as 10 putative novel class I gene products, detected on the basis of their association with β_2-microglobulin, may be encoded by genes dispersed between the mapped and unmapped cosmid gene clusters. In one case, antibodies to a novel class I antigen apparently detect the corresponding antigen expressed at low levels on BALB/c spleen cells.

We thank Drs Shen and Boyse for the gift of the monoclonal antibodies to TL, Drs Hansen and Sachs for the antibodies to the class I antigens, Lorraine Flaherty for the monoclonal antibodies to Qa-2 and Dr Michael Hunkapiller for rabbit antiserum to rat β_2-microglobulin. Dr Michael Steinmetz and Mr Henry Sun are acknowledged for supplying clone DNA, Ms Marie Krempin for assisting with tissue culture, Dr Jeffrey Frelinger for supplying the congeneic mice, Dr Anders Örn for technical assistance, Drs Iwona Stroynowski, Ellen Kraig, Mitch Kronenberg, Ellen Rothenberg, Jane Parnes, Jim Forman and Jeffrey Frelinger for their helpful discussions, and Bernita Larsh for the preparation of the manuscript. This research was supported by NIH grants GM 06965, CA 22662, CA 22199 and CA 25911.

Measurements on a shock wave generated by a solar flare

Alan Maxwell

Murray Dryer

Space Environment Laboratory, NOAA, Boulder,
Colorado 80303, USA

Shock waves generated by intense solar flares may be driven by a large amount of ejected mass, about 5×10^{16} g, and the total energy involved may be of the order of 10^{32} erg. The shocks may have initial velocities of the order of 2,000 km s^{-1} and, in their exodus through the corona, may be accompanied by fast-moving optical transients, the emission of highly characteristic radio signatures and the acceleration of particles to quasi-relativistic velocities[1]. Here we review data on a high-velocity shock generated by a flare on 18 August 1979, 1400 UT, comment on some previously deduced velocities for the shock[2], and then present a model, based on current computer programs to account for the overall characteristics of the shock as it propagated through the corona and the interplanetary plasma.

The solar flare that occurred on 18 August 1979 at 1400 UT was one of the more energetic flares of the current solar cycle. Optically, the flare was not well observed because it occurred just behind the east limb at heliographic latitude N08°. Nevertheless, it gave rise to significant X-ray and radio emission, as well as to a high-velocity shock. The shock was tracked by its radio emission of spectral type II, first by radio spectral equipment (25–580 MHz) at the Harvard Radio Astronomy Station, Fort Davis, Texas, and then by low-frequency equipment (0.03–2 MHz) on the ISEE 3 satellite[3]. It impinged on the Earth's magnetosphere some 40 h later, giving rise to the sudden commencement of a magnetic storm. Data on the outward-travelling shock were also acquired at a point $13.1R_0$ from the Sun by a technique described by Woo and Armstrong[2]. Their velocity estimates were obtained by examination of the effects of the shock and its driver-piston on signals transmitted at 2.3 and 8.4 GHz from the Voyager 1 spacecraft and received on Earth. At the time of the flare, the line of sight from Voyager 1 to Earth passed within 13 R_0 of the Sun and, when the shock passed this point, abrupt changes began in the radio signals received from the spacecraft, as may be seen in Fig. 1.

In applying the Rankine–Hugoniot relations to determine the shock velocity at 13 R_0, Woo and Armstrong suggested using a pre-shock velocity of 200 km s^{-1}, with which we agree,

0028–0836/82/460237—03$01.00

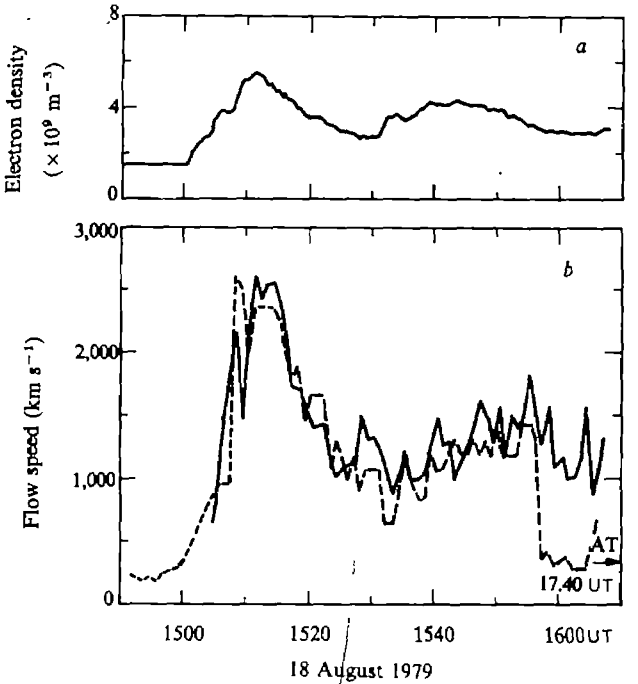

Fig. 1 Plasma data at 13.1 $R_\odot$ ($R_\odot$ = radius of the Sun) derived from changes in radio transmissions from Voyager 1, at the time of passage of the flare-generated shock. *a*, Changes in electron density; *b*, changes in flow speed (after ref. 2). Dashed line, log amplitude scintillations; solid line, spectral broadening.

and a post-shock velocity of 2,600 km s^{-1}, which, based on the data of Fig. 1, we believe to be too high. We suggest that the flow velocity of 2,600 km s^{-1} measured at 1510 UT by Woo and Armstrong refers to the plasma velocity substantially behind the shock, whereas the proper application of the Rankine–Hugoniot relations requires use of a velocity immediately behind the shock. We suggest the shock probably passed the 13 R_0 point at 1500 UT, that its passage probably took <10 s, and that everything seen thereafter in Fig. 1 refers to the region of intense turbulence behind the shock. The 10-s period also represents an upper limit and is derived on the assumption that the shock thickness is, at most, of the order of 1–10 ion gyroradii[4,5]. In view of our ignorance of magnetic field strength and direction in the shock, we use a roughly equivalent estimate of 10–100 ion inertial lengths[4,5]. Using the pre-shock electron density of 1.5×10^9 electrons m^{-3} given by Woo and Armstrong, and assuming that the electron density equals the ion density, we find the ion inertial length ($c/\omega_{\rm pi}$, where c is the velocity of light and $\omega_{\rm pi}$ the ion plasma frequency) to be 6 km and hence deduce the shock thickness to be of the order of 60–600 km. For a shock travelling at about 2,000 km s^{-1} the front would thus pass the line of sight in ~1 s—literally in a flash. We therefore choose the period 1502–1504 UT in Fig. 1, to determine the post-shock velocity, which would thus be of the order of 1,000–1,500 km s^{-1}. Assuming conservation of mass through the shock and the pre-shock electron density and velocity given by Woo and Armstrong, we then determine the shock velocity as follows. Assume that the pre-shock velocity $v_1 = 200$ km s^{-1}, the post-shock velocity $v_2 = 1{,}250$ km s^{-1}, the pre-shock electron density $n_1 = 1.5\times10^9$ electrons m^{-3}, and the post-shock electron density $n_2 = 3.0\times10^9$ electrons m^{-3}. The shock velocity then equals $(v_2n_2 - v_1n_1)/(n_2 - n_1) = 2{,}300$ km s^{-1} approximately, rather than the value of 3,500 km s^{-1} derived by Woo and Armstrong.

In a second estimate of the shock velocity, based on its transit time from the flare region to 13 R_0, Woo and Armstrong noted that "shock arrival occurs at approximately 1501 UT and based on the transit time from the Sun to 13.1 R_0 we obtain a shock speed of 3,509 km s^{-1}", but they made no specific reference to the starting time of the shock in the vicinity of the solar flare. There are, however, four separate lines of evidence that indicate that the explosive phase of the flare, which we take to be the starting time of the shock, occurred at approximately 1402 UT. A transit time of 60 min for a shock to reach 13 R_0 then translates into an average velocity of 2,350 km s^{-1}. The evidence relating to the explosive phase of the flare, shown in Fig. 2, is as follows: (1) an abrupt increase in radio centimetric emission began at approximately 1402 UT and this was followed by a burst of 45 min duration and of considerable energy. (2) Hard X-ray emission showed a sudden increase over the period 1359–1401 UT. (3) A metric radio type II burst was recorded over the period 1412–1423 UT and statistical surveys repeatedly show that type II bursts in the metre band are first seen about 6–10 min after the explosive phase of a flare[6] (this delay corresponds to the time taken by a shock to travel from the region of energy release in the low corona to the heights at which metric type II radio bursts are generated), which again suggests a start time for the shock of about 1402 UT. (4) Type III radio bursts, probably associated with the explosive phase of the flare, were recorded at 1402–1404 UT. (Figure 2 also shows a small radio burst in the centimetre band and an accompanying X-ray burst at 1345 UT. We believe, as do other investigators (S. Kane personal communication), that this burst was a precursor to the main event. If it did, however, signify the start time of the shock, the transit time of the shock to 13 R_0 would be 15 min longer and the deduced average shock velocity would be even less than 2,350 km s^{-1}.)

A shock velocity of 2,300 km s^{-1}, rather than the velocity of 3,500 km s^{-1} derived by Woo and Armstrong, agrees somewhat better, we feel, with existing models for propagation of flare-generated shocks from the Sun to the Earth. For this particular flare, the propagation time of the shock between the Sun and the Earth was 40 h. (The shock reached the ISEE 3 satellite, located at the lagrangian point between the Sun and the Earth,

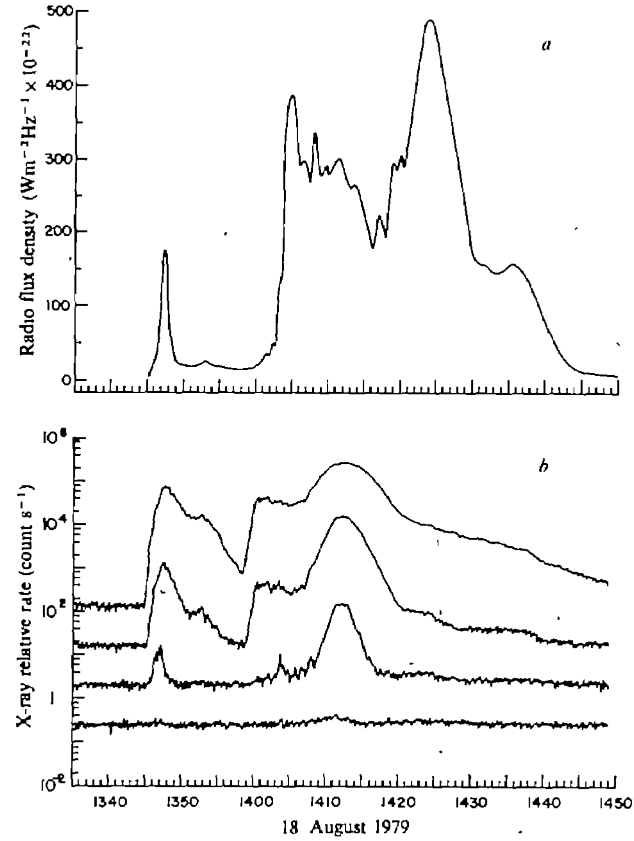

Fig. 2 Radio and X-ray emission from E-limb solar flare of 18 August 1979, 1400 UT. *a*, Radio burst at 2,800 MHz. *b* X-ray bursts recorded by ISEE 3 satellite; reading from top to bottom, the X-ray curves cover the energy ranges 26–43, 43–78, 78–154 and 154–398 keV, respectively.

on 20 August 1979 at 0550 UT[2] and the Earth at 0625 UT.) Bearing in mind that the flare occurred at heliographic longitude ~E 90, we suggest that, to reach the Earth, the shock must have had a wide angular extent and very considerable energy. We suggest that it had an initial velocity of the order of 2,300 km s^{-1} and that, while ascending through the corona it was accelerating electrons to quasi-relativistic energies and generating X rays (identifiable in Fig. 2 by the marked increase in X rays over the period 1407–1420 UT, at the time of the observed type II radio burst). The shock was then driven at a constant velocity of ~2,300 km s^{-1} to a distance of about 75 R_0 (S. Kane, personal communication), after which it propagated through the solar wind to the Earth as a blast wave, reaching the Earth ~40 h after the flare with a velocity of 750 km s^{-1}. The average deceleration between 75 and 215 R_0 was thus 0.012 km s^{-2}, which is consistent with previously estimated values for the deceleration of shocks between the Sun and the Earth[7,8]. We also note that the wide helio-longitudinal extent of the shock probably represents the rule, rather than the exception, for flare-generated shocks.

The X-ray data in Fig. 2 are reproduced by kind permission of Dr Sharad Kane, Space Sciences Laboratory, University of California, Berkeley. The centimetric radio data in Fig. 2 were provided by courtesy of Dr M. B. Bell, Astrophysics Branch, National Research Council, Ottawa. The work of Alan Maxwell described in this paper was carried out under NASA grant NSG-7648 and NSF grant ATM 80-07024.

Coronagraphic observations of two new sungrazing comets

N. R. Sheeley Jr, R. A. Howard, M. J. Koomen* & D. J. Michels

E. O. Hulburt Center for Space Research,
Naval Research Laboratory, Washington DC 20375, USA

We recently reported the discovery[1] of a comet (Howard-Koomen-Michels: 1979 XI) that apparently collided with the Sun on 30 August 1979. We now report observations of two additional sungrazers that encountered the Sun on 27 January 1981 and 20 July 1981, respectively. Like comet 1979 XI, these two new comets seem to have been members of the Kreutz group of sungrazers[2–4], and like 1979 XI the new comets did not reappear after their encounters with the Sun. The discovery of three previously unreported comets during the initial 2.3 yr of our satellite coronal observations leads us to suspect that sungrazers are much more common than one might suppose from the list of only nine known sungrazers observed during the years 1668–1970[5,6].

Our observations were obtained with the Naval Research Laboratory's Earth-orbiting SOLWIND coronagraph. This instrument has been operating routinely on the US Air Force Space Test Program satellite, P78-1, since March 1979. Its broadband (4,100–6,350 Å) images show a Sun-centred annular field of view from 2.5 to 10.0 $R_\odot$ with a spatial resolution (pixel separation) of 1.25 arc min and with sensitivity adequate to record features having more than 10^{-10} times the brightness of the solar photosphere. In its normal operating mode, SOLWIND has obtained full-frame coronal images at 10-min intervals during the 1 h sunlit portion of each 97-min satellite orbit. This instrument and its initial observations have been discussed in detail elsewhere[1,7,8].

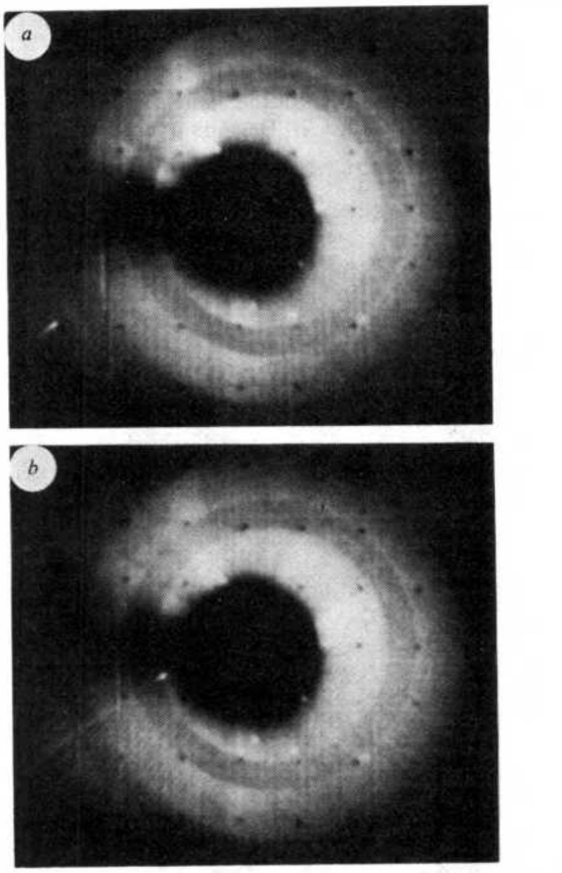

Fig. 1 The comet as seen against a background of the quiescent solar corona. *a*, The first frame in which the comet was detected, was recorded by the SOLWIND satellite coronagraph at 2039 UT on 26 January 1981. It shows the coma at a 7.9 $R_\odot$ projected distance from the Sun's centre. Subsequently, the coma dimmed noticeably (see Fig. 2 and discussion in the text), but it flared brightly again in *b* at 0020 UT 27 January 1981, just before passing behind the coronagraph's occulting disk, at 2.5 $R_\odot$. The dark, nearly concentric rings surrounding the occulter shadow are polarization analysers in the instrument's focal plane. Solar north is at the top in each frame, and east to the left.

In Fig. 1, the coronal images at 2039 UT 26 January 1981 and 0020 UT 27 January 1981 show the second of the three comets that we have observed with the SOLWIND coronagraph. The bright coma and fainter tail are visible as the comet approached the Sun from the south-east (lower left). In each image, the central dark area is the shadow of the instrument's occulting disk that artificially eclipses the Sun, and the dark region extending to the left is the shadow of the occulter support. The two dark, nearly concentric rings surrounding the occulter shadow are polarization analysers in the focal plane. They pass light that is polarized only in the radial direction, while the remaining regions pass light that is polarized only tangentially, thus favouring the Thomson-scattered light from free electrons in the Sun's *K*-corona. Note that the comet's light does not appear to be polarized, but that the bright coronal streamer in the north-east (upper left) is strongly blocked by the analyser rings.

We obtained 15 such images of this comet as it approached the Sun at a projected speed of 250 km s^{-1} before disappearing behind the occulting disk. Figure 2 shows a partial sequence of these images during 2039 UT 26 January–0030 UT 27 January 1981, and also includes an image at 0654 UT 27 January by which time the comet's nucleus should have reappeared from behind the occulting disk. In each image, the white disk was introduced to indicate the approximate size and location of the occulted photosphere. Also, unlike the images in Fig. 1,

these images in Fig. 2 are difference images that show only intensity changes since 1300 UT on 26 January, before the comet's entrance into the field of view.

The temporal variation of the coma's apparent brightness is clearly visible in Fig. 2. Beginning around 2039 UT, the apparent brightness decreased steadily until 2351 UT after which it increased substantially as the comet came within a few radii of the Sun. Although we have not yet performed quantitative photometry, we think that the initial brightness decrease is a real effect and not simply the result of the radial decrease of the instrument's transmission function as one approaches the Sun. A comparison with stars and planets of known brightness suggests that the coma's brightness changed from a magnitude of roughly 0.0 at $8 R_{\odot}$ to $+1.0$ at $5.5 R_{\odot}$, and finally to -2.5 or brighter at $3 R_{\odot}$. Thus, unlike our first comet (1979 XI) whose magnitude reached approximately -3.5, this second comet was relatively faint during its initial approach to the Sun. This may be why it has not been reported previously despite the optimal position of its orbit relative to the Earth in the months before 26 January 1981. Of course, the fact that the comet did not reappear after perihelion accounts for why it was not observed in the months following 27 January 1981. Indeed, the sudden flare up of brightness around 0030 UT 27 January may indicate the beginning of the comet's final demise as it neared the Sun.

The 15 pre-occultation images were obtained during a scant 231-min interval with a spatial resolution (pixel separation) of 1.25 arc min and with modest absolute positional errors associated with image distortion and uncertainties in spacecraft roll angle. Consequently, it is difficult to determine the orbital elements uniquely, or even to distinguish between a retrograde orbit (motion counter to that of the planets around the Sun) or a so-called direct (prograde) orbit. Nevertheless, using the same technique that we applied to the observations of our first comet (1979 XI)[1], we have been able to find a small range of possible orbits (as a function of perihelion distance as a parameter) that fit the 15 pre-occultation observations within our

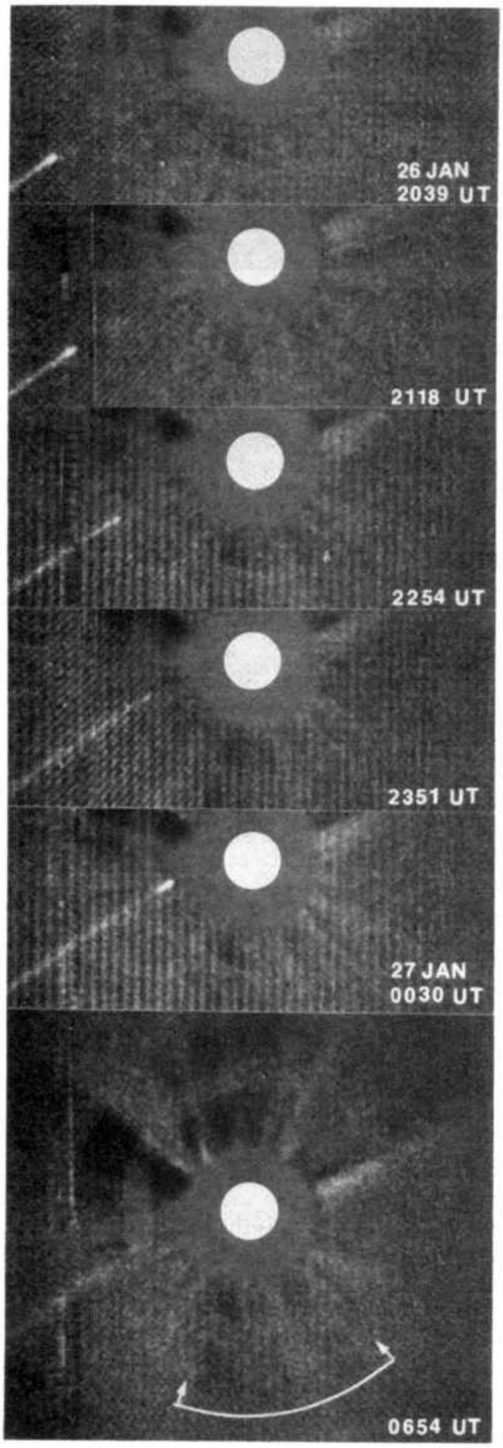

Fig. 2 Variations in the brightness of the coma are easily discernible in the first five frames, showing approach of the comet to perihelion. The sixth frame, after perihelion, shows a wider portion of the field at 0654 UT on 27 January. The arrows indicate a region in the corona through which the comet would have passed, had it survived perihelion, but no vestige of the coma was observed after the frame at 0030 UT 27 January. The photos in this sequence are difference images, showing only changes in the coronal scene after about 1300 UT on 26 January. A white disk has been added to each frame to indicate the location and size of the Sun, which is hidden by the coronagraph's occulting disk. The radial light and dark spoke-like features represent evolutionary increases and decreases, respectively, in the intensity of coronal streamers.

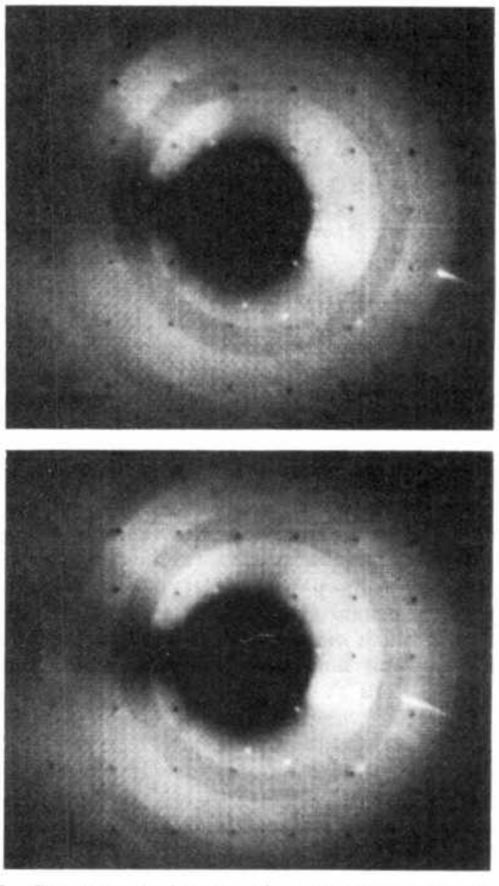

Fig. 3 Coronagraph images of a sungrazing comet as it approached the Sun from the south-west at 0209 UT and 0354 UT 20 July 1981. The format is the same as that in Fig. 1 with solar north approximately up and west approximately to the right. Unlike coronal streamers, whose polarized Thomson scattered emission is cut off by the dark polarizing rings, the comet is largely unpolarized and remains bright as it passes across the rings.

measurement accuracy. A retrograde orbit having a perihelion distance of $\sim 1.5\ R_\odot$, a perihelion time of 0230 UT 27 January, and orientation angles representative of the Kreutz group is consistent with our observations. [Marsden[9] has used our measurements to deduce a perihelion distance of $1.05\ R_\odot$, a perihelion time of 0149 UT 27 January 1981, and the orbital angular elements $\Omega = 350°$, $\omega = 72°$, and $i = 143°$ assuming that the comet's perihelion direction agrees with that of the Kreutz group.]

In Fig. 2, the area marked by arrows on the image at 0654 UT shows the region through which the comet would have moved outward from the Sun during the morning of 27 January 1981 if its perihelion distance lay in the range $1\text{–}2\ R_\odot$. Regardless of which of these representative orbits is assumed, the outbound coma should be visible in this image, but it is not. Nor was it visible on any other image obtained during 0001–1100 UT on 27 January 1981. Evidently, the comet either hit the Sun or was destroyed (or at least purged of its volatile material) in a close encounter. However, this does not explain why the 'outbound' tail was not visible after perihelion as it was with comet 1979 XI which we suppose hit the Sun[1]. At 0654 UT one can see only the fading trace of the tail along the inbound track together with some obvious coronal streamer changes, especially prominent in the Sun's northern hemisphere. It is possible that an 'outbound' tail, if it existed, would be undetectable for this relatively faint comet.

Figures 3 and 4 show similar observations of the third sungrazing comet that we have seen with the SOLWIND coronagraph. Figure 3 shows that the head of this comet is not cut off by the polarizing ring so that, like the first two comets, it is largely unpolarized. By comparison with a previously recorded image of the planet Mercury on 28 December 1980, we estimate that this third comet had a magnitude of -0.8 at $8\ R_\odot$.

More than 15 images were obtained before occultation on 20 July 1981, and numerous additional images were obtained during the subsequent day. The comet approached the Sun with a projected speed of $\sim 160\ \text{km s}^{-1}$ during 0029–0354 UT. As for the first two comets, our analysis of these images gave an orbit, which, if assumed to be retrograde, is consistent with those of the Kreutz group, this time with a perihelion of $\sim 1.2\ R_\odot$. Its perihelion time would have been 0805 UT 20 July, nearly the time of the fifth image in Fig. 4 in which the arrow marks the uneclipsed end of the comet's gradually lengthening tail. [Marsden[10] deduced a similar orbit with a perihelion distance of $0.9\ R_\odot$, a perihelion time of 0742 UT 20 July, 1981, and orbital angular elements $\Omega = 350°$, $\omega = 74°$, and $i = 143°$ again assuming that the perihelion direction agrees with that of the Kreutz group.] We suppose that the relatively short, tear-drop shape of this comet's tail is due in part to a perspective effect associated with the more oblique (head-on) orientation of the orbital axis relative to the line of sight than was obtained for the first two comets.

Finally, like our first two comets, this third sungrazer never reappeared after its occultation, and like the second comet (Fig. 1) no post-perihelion dust cloud was visible. In Fig. 4, the difference image at 2225 UT shows only coronal enhancements and depletions that have occurred in the 24 h since 2200 UT 19 July. The greatest enhancement lies in the south-east where the comet's head should have reappeared if its perihelion were in the range $1\text{–}2\ R_\odot$. However, this enhancement represents the accumulated evolution of a slowly brightening coronal structure whose initial growth is faintly visible in the earlier images in Fig. 4 well before this comet reached the Sun.

Perhaps the importance of these new observations is to suggest that sungrazing cometary encounters may be relatively frequent. Before the beginning of SOLWIND operation in March 1979, nine Kreutz sungrazers had been reported during the years 1668–1970. Since March 1979, we have seen three additional sungrazers despite the fact that we have processed coronal images for only 500 days to date (July 1982). Significantly, none of these three sungrazers was seen from the ground[11]. Evidently the SOLWIND coronagraph is observing

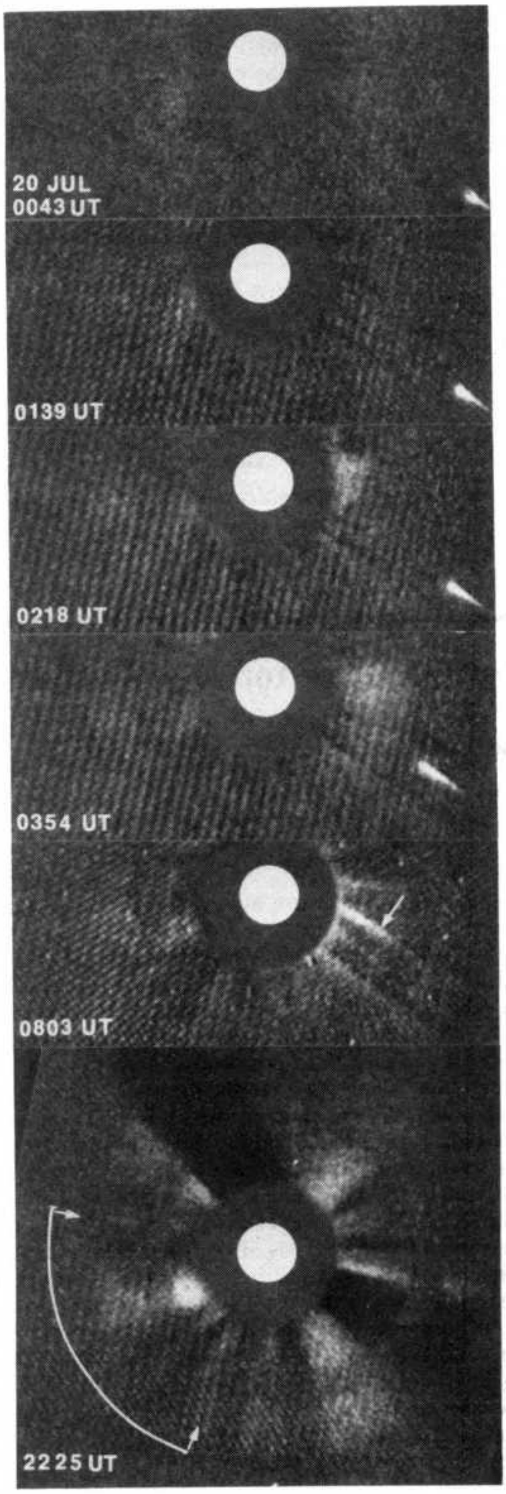

Fig. 4 A sequence of difference images showing intensity changes in the coronagraph field of view since 2200 UT 19 July 1981. Solar north is up and west is to the right. The inbound comet is clearly visible during 0043–0354 UT 20 July as it approached the Sun from the south-west. Its tail is still visible at 0803 UT (arrow) by which time the head has passed behind the occulting disk. By 2225 UT, there is no trace of either head or tail among the numerous increases and decreases of coronal intensity. The greatest enhancement, visible in the south-east where the comet's head is expected to reappear (arrows), represents the accumulated brightness increase of a coronal structure whose initial brightening is already faintly visible in the pre-occultation frames of this figure. The white disk at the centre of each image indicates the apparent size and location of the occulted photosphere.

the faintest and perhaps most perishable fragments of the supposed primordial comet whose close encounter with the Sun may have led to the formation of the Kreutz group.

We acknowledge the DOD Space Test Program for P78-1 spacecraft integration, launch, and operational support, and NASA both for spare coronagraph and solar pointing hardware from its OSO 7 programme and for financial support through DPR W-14,429. A dispersion law for solar oscillations

Thomas L. Duvall Jr*

Laboratory for Astronomy and Solar Physics, NASA,
Goddard Space Flight Center, Greenbelt, Maryland 20771, USA

The pressure or *p*-modes are acoustic vibrations trapped in a resonant cavity below the solar surface. The waves are most easily observed as primarily vertical velocities at the solar surface by Doppler shift techniques. The vertical velocities vary harmonically in time and in space across the solar surface. These harmonic variations lead to a natural description of the oscillation modes in terms of their positions in a diagram of temporal frequency (ω) versus horizontal spatial frequency (k_h). Observationally, the positions in the k_h–ω diagram are determined from a two-dimensional power spectrum of a series of Doppler shifts of a solar spectrum line measured equidistant in space and time. An example of the observed positions is shown in Fig. 1 (see ref. 1). Theoretically, the mode positions are determined by an analysis of the solar cavity, including an uncertain model of the solar interior. Most theoretical work has consisted of numerical solutions of the equations of motion leading to predicted positions in the k_h–ω diagram (see, for instance, ref. 2). This approach has been reasonably successful, yielding inferences about the depth of the convection zone[3]. Here we compare a simple model of the oscillations discussed by Leibacher and Stein[4] with observations.

In the Leibacher and Stein[4] model the resonant cavity is a spherical shell. To first order the outer boundary of the shell is considered to be the same for all modes and is defined by the sharp decline in the density scale height just below the visible surface. The inner boundary of the shell is caused by the increase of sound speed with depth. Waves travelling downwards at an oblique angle to the vertical (with non-zero horizontal wavenumber k_h) are refracted away from the vertical by the increasing sound speed. At some depth the propagation becomes horizontal and the wave is reflected, this marking the lower boundary of the cavity. At this depth the sound speed is equal to the horizontal phase velocity ω/k_h. Leibacher and Stein[3] argue that the boundary conditions should be similar to an organ pipe closed at one end and open at the other. The WKB approximation is then used to derive the condition: $(n+1/2)\pi/\omega = \int dz/c$. Where z is the vertical coordinate, c is the speed of sound and n is the number of nodes in the vertical standing wave patterns. The integral is over the depth of the cavity. $\int dz/c$ is the travel time of sound across the cavity. The constant 1/2 depends on the choice of boundary conditions[5]. The different curves in Fig. 1 correspond to different values of n while distance along a given curve corresponds to cavities of different depths.

From this simple model we draw two conclusions. (1) If the top of the cavity is the same for all modes and the bottom of the cavity is defined by the position where $c = \omega/k_h$, then modes in different parts of the k_h–ω diagram with the same value of ω/k_h are trapped in an identical cavity. (2) If the cavity is identical, the travel time of sound across the cavity will be the same for different modes. Therefore, in a plot of ω/k_h (an observed quantity) versus $(n+1/2)\pi/\omega$ (another observed quantity), the ridge structure of Fig. 1 should collapse onto a single curve. This leads to a modified dispersion law of the form $(n+1/2)\pi/\omega = f(\omega/k_h)$.

Using this procedure we found that the ridge structure did not collapse onto a single curve. To admit the possibility of other boundary conditions similar plots were constructed, but with the ordinate given by $(n+\alpha)\pi/\omega$, for different values of α. It was found that near $\alpha = 3/2$ the points collapse onto a single curve, within the observational accuracy (Fig. 2). To determine a best value for α the residual variances to fifth-order polynomial fits to the resulting points was computed as a function of α. The minimum residual variance (or the tightest curve) was found for the value $\alpha = 1.50$. The standard deviation of the points about the polynomial fit is 1% of the mean value of $(n+3/2)\pi/\omega$. The fundamental mode ($n = 0$) has been excluded from this analysis and from Fig. 2 as its frequencies do not fall along the curve of Fig. 2.

An important aspect of the above result is the reduction of the redundancy in the k_h–ω diagram. Essentially all of the information about the solar interior contained in the multiple curves of Fig. 1 is concentrated in the single curve of Fig. 2. Modes trapped in an identical cavity are giving redundant information, and the result of Fig. 2 strongly suggests that modes with the same value of ω/k_h are trapped in an identical cavity. This is surprising, as the assumption of an identical boundary at the top for all modes is really a gross simplification of the problem. The upper boundary should really depend on

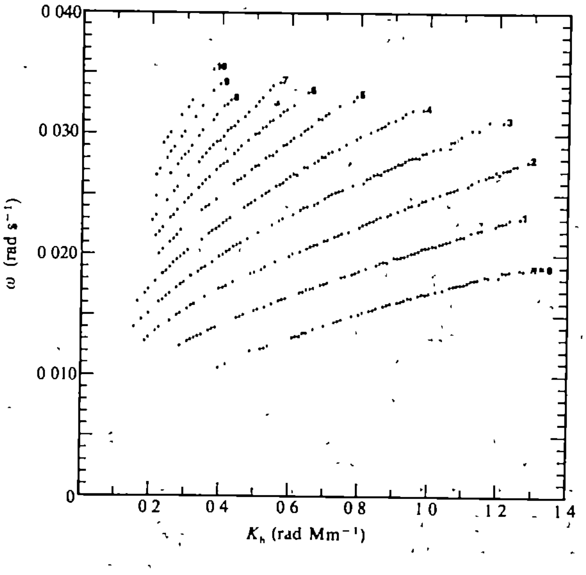

Fig. 1 Mode frequencies derived by a centroid analysis from a two-dimensional (ω, k_h) power spectrum of velocity observations made at Kitt Peak in May 1980 (ref. 1). The curves are labelled with the radial harmonic number n. Solar rotation has been cancelled by averaging the frequencies ω for eastward and westward propagating waves.

* Present address Kitt Peak National Observatory, 950 N Cherry Avenue, Tucson, Arizona 85726, USA

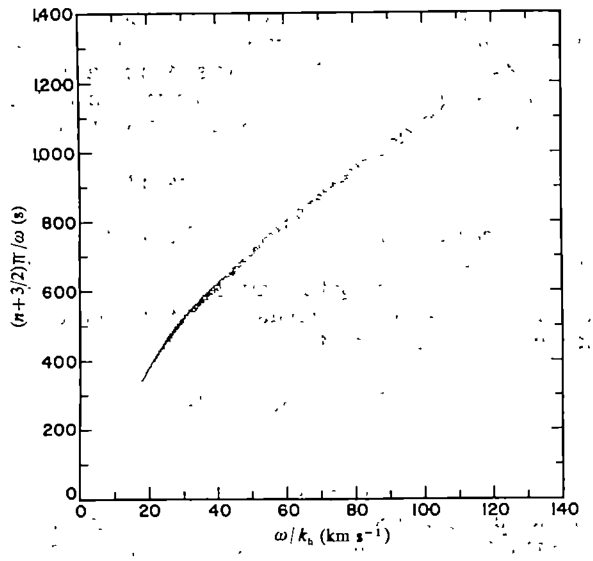

Fig. 2 Plot of $(n+3/2)\pi/\omega$ against ω/k_h for the mode positions of Fig. 1. The $n = 0$ modes are excluded.

ω (ref. 6). The above result suggests that the difference in boundary conditions at the top for different modes has a minimal effect on the resulting frequencies.

To within the observational accuracy the best value of α is 3/2. This may be fortuitous, but it does admit the possibility that the Leibacher and Stein analysis is correct and that we have misidentified the radial node number n. This seems unlikely because of the general agreement between the theory and observed frequencies. However, n is not observed directly but is inferred from this general agreement. So n misidentification is possible though unlikely.

Another possible source of the value $\alpha = 1.50$ is the atmospheric structure. Christensen-Dalsgaard[7] has shown that for a polytrope of index m the frequencies obey a relation $\omega/k \propto [(n+m/2)/\omega]f(n, m)$, where $f(n, m)$ has a weak dependence on n and a dependence on other atmospheric structure parameters. If we could assign a polytropic index $m = 3$ for the solar convection zone, we could approach the result of Fig. 2. However, the polytropic index is a strong function of position in the upper convection zone according to current models. Also, the function $f(n, m)$ for $m = 3$ introduces differences between modes of different n that are larger than the observed scatter in Fig. 2. Although the polytropic model may not be directly applicable, it does point out a way of getting a dispersion law that is dependent on the atmospheric structure.

We have considered whether the data might be better fitted by an α which is a function of another parameter, possibly ω/k_h or ω. However, the data are fitted to the observational accuracy by a constant α and so we have not felt justified in introducing further dependencies.

If the ordinate of Fig. 2 is the travel time of sound across the cavity and the abscissa the speed of sound at the bottom of the cavity, the data of Fig. 2 could be directly inverted to obtain the speed of sound plotted against depth. We are investigating this possibility.

I thank Drs Harvey and Rhodes for the use of unpublished data, and Pat Lambotte for typing the manuscript.

Critical density fluctuations within a single polymer chain

Izumi Nishio, Gerald Swislow, Shao-Tang Sun & Toyoichi Tanaka

Department of Physics, and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

The coil–globule phase transition is a reversible, conformational change of a macromolecule where the high temperature (or good solvent) phase is an extended coil and the low temperature (or poor solvent) phase is a tightly packed globule[1]. We now present direct observations, made by photon-correlation spectroscopy, of the sharp increase in amplitude and relaxation time of density fluctuations within a single polymer molecule as it passes through the coil–globule phase transition. This growth of fluctuations is characteristic of critical phenomena associated with phase transitions, a subject that has generated much interest over the past decade, and has been studied in a wide variety of physical systems. These are the first measurements of critical behaviour that we know of made on a three-dimensional system that can be characterized as finite in the terms of statistical mechanics.

The phase transition is a manifestation of competition between two forces acting on the polymer chain. Affinity among polymer segments tends to shrink the polymer, while an entropic pressure originating from the thermal motion of the individual segments tends to expand it. At higher temperatures

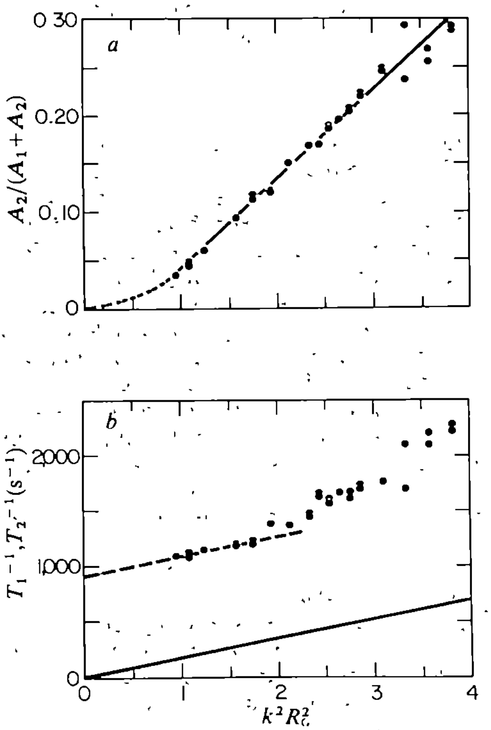

Fig. 1 Characteristics of intramolecular fluctuations at 33.9 °C plotted as a function of the parameter $x = k^2R_G^2$. *a*, The normalized amplitude. *b*, The frequency of internal motion. The solid line is the frequency associated with the translational diffusion. Points representing the frequency of the lowest order mode of internal motion fall parallel to the solid line at small values of x.

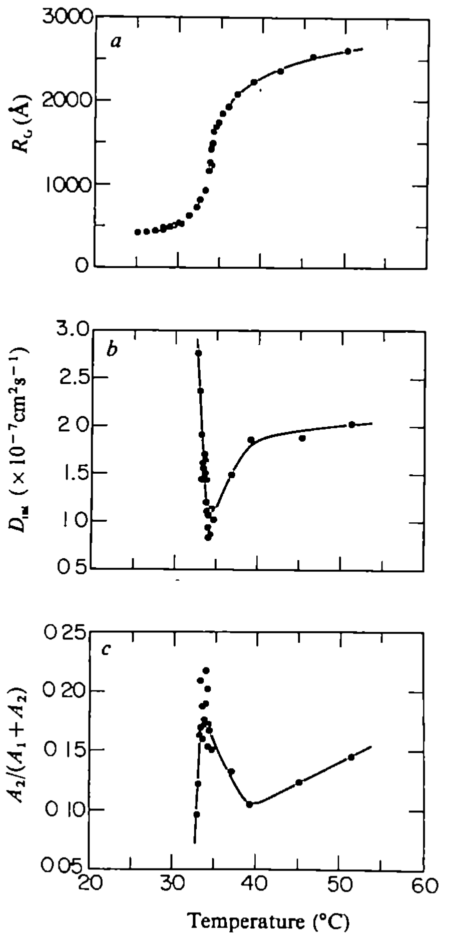

Fig. 2 The behaviour of the intramolecular fluctuations as a function of temperature (lines to guide the eye). *a*, The collapse seen in the radius of gyration. *b*, The internal diffusivity of the segments, $D_{int}=R_G^2(T_2^{-1}-T_1^{-1})$. *c*, The amplitude of the fluctuations at $x = 2.5$.

(or in a good solvent) the entropic pressure dominates the segment affinity, and the polymer is expanded. At lower temperatures (or in a poor solvent) the segment affinity is dominant, and the polymer collapses. For flexible polymers of large molecular weight the collapse is quite drastic[2-4]. The polymer conformation is not frozen in during the process of collapse, however. Individual segments along the polymer backbone undergo thermal motion resulting in intramolecular concentration fluctuations. The brownian diffusion of the macromolecules as a whole through the solvent also creates concentration fluctuations, but on a longer time and length scale. The autocorrelation function of light scattered from the polymer solution contains information from both sources. The amplitude and relaxation time of intramolecular fluctuations can be determined by careful analysis of the correlation function at various scattering angles.

The polymer–solvent system used in the experiment is polystyrene (Polysciences $\bar{M}_W=2.6\times10^7$, $\bar{M}_W/\bar{M}_N=1.3$) in cyclohexane ($T_\theta = 35.4$ °C). The light scattering apparatus is of typical construction. The sample solution's temperature stability could be maintained to within a couple of mK over a period of several days. This is especially important in the region of the transition, where polymer size changes drastically with temperature. The sample was sufficiently dilute ($\sim10^{-6}$ g ml^{-1}) so that the collapsing polymers would remain dispersed without aggregation.

Different length scales can be probed by varying the angle of collection of photons scattered by the polymer solution. The length scale is determined by the inverse of the scattering vector, $k=(4\pi/\lambda)\sin(\theta/2)$, where λ is the incident wavelength in the solution, and θ is the scattering angle. A useful parameter for characterizing the length scale is $x=k^2R_G^2$, where R_G is the polymer radius of gyration. At forward scattering angles where $x<1$, only length scales larger than the molecular size are probed; the correlation function is a single exponential,

$$g^{(2)}(t)\propto\exp(-2Dk^2t)+\text{constant}$$

where D is the translational diffusion coefficient of the polymer. Shorter distances are probed in the range $1<x<4$. The lowest internal mode representing fluctuations in the overall polymer size contributes to the correlation function, which is now described by two components,

$$g^{(2)}(t)\propto\exp(-2Dk^2t)\{P_0(x)+P_1(x)\exp(-t/\tau)\}^2$$
$$+\text{constant}$$

where τ is the relaxation time of the lowest mode[5,6].

An established procedure was used to characterize the internal motion[7,8]. At each temperature, correlation functions were measured at forward scattering angles ($x<1$) to determine D. The correlation function was then measured at the higher scattering angles and fit to

$$c(t)=\{A_1\exp(t/T_1)+A_2\exp(t/T_2)\}^2+B$$

where T_1 is fixed by D. The parameters A_1, A_2, T_1, and B were varied.

Figure 1*a* shows the behaviour of the normalized amplitude of the internal motion, $A_2/(A_1+A_2)$, as a function of x at 33.9 °C. Figure 1*b* shows the inverse relaxation time, T_2^{-1}, also as a function of x at the same temperature. The translational relaxation time T_1^{-1} is plotted as a straight line through the origin in Fig. 1*b*. The value of τ is obtained from the difference in T_1^{-1} and T_2^{-1} in the region where they are parallel. For higher values of x, the effect of the higher-order modes corresponding to shorter length-scale density fluctuations is apparent—the two-exponential form is no longer appropriate to describe the measured correlation function. Figure 2*a* reproduces our previously published results showing the collapse in the radius of gyration as temperature is lowered[4]. Figure 2*b* is a plot of the diffusivity of the internal motion defined as $D_{int}=R_G^2/\tau$, derived from the relaxation time of the intramolecular fluctuations versus temperature. This combination of R_G and τ is appropriate since τ scales in proportion to R_G^2, and because the proportionality coefficient D_{int} actually represents the intramolecular segment diffusivity[5,9]. The slowing intramolecular motion is quite apparent in this plot. Figure 2*c* is the normalized amplitude $A_2/(A_1+A_2)$ versus temperature at $x=2.5$, indicating an approach to critical divergence.

More precise measurements of this phenomenon are underway. Future experiments that use carefully prepared monodisperse polymers in a range of molecular weights to measure the effect of the size of the statistical system on the critical behaviour would prove interesting. The physics of the polymer conformational fluctuations in the vicinity of the collapse phase transition may also prove useful in describing the function of certain biological macromolecules.

Meandering of the subtropical front south-east of the Azores

R. H. Käse & G. Siedler

Institut für Meereskunde, Düsternbrooker Weg 20, 2300 Kiel, FRG

A subtropical front was observed in the area south and south-east of the Azores during cruises of FS *Meteor* and FS *Poseidon* in early 1982. The front has a basically west–east extension, with considerable meandering observed. Meso-scale eddies are found on both sides. The overall flow pattern corresponds to earlier results on geopotential differences in the upper north-east Atlantic, but the baroclinic transport of the order of $10^7\ m^3\ s^{-1}$ is found to be concentrated in a 60-km wide jet. We suggest here that the current band is part of the gyre circulation, resulting from a branching of the North Atlantic Current.

Such subtropical fronts can be expected where strong Ekman transport convergence occurs in a region of large horizontal thermohaline or haline gradients. They are temperature and salinity fronts in winter and spring and salinity fronts only in summer and autumn in the North Pacific[1], with a density front existing simultaneously at both times of the year. Jet-like baroclinic surface currents have been found at a 1,000-km long front in the central subtropical North Atlantic, with current speeds as high as 50 cm s^{-1} (ref. 2). The subtropical front is more pronounced in the Southern Hemisphere, and a complicated mesoscale structure connected to the front has been found in the southern Indian Ocean[3].

The subtropical front also marks the transition between the eastward and westward flow in the oceanwide anticyclonic gyre circulation. Early studies of the North Atlantic circulation in the area north of the Azores[4,6] led to the conclusion that the North Atlantic Current splits into two branches at approximately 45° N, 25° W, with a southern branch heading towards the Azores and continuing south-east towards Madeira. The upper ocean flow field can most easily be seen in the potential density field in Fig. 77 of ref. 6, indicating a splitting-up into two more branches west of the Azores. An eastern branch in this historical map flows southward to the Azores, then veers left towards the south-east. A second branch reaches the Azores west of the Mid-Atlantic Ridge, oriented west at first at 37° N and turns back to the east at 35° N. Note that Hansen's[5] numerical model of Atlantic Ocean surface currents including a variable wind field produced a dynamic topography that is consistent with a flow from the Azores to the Madeira region. A similar basic pattern can be found in more recent maps of upper ocean geopotential differences[7–9].

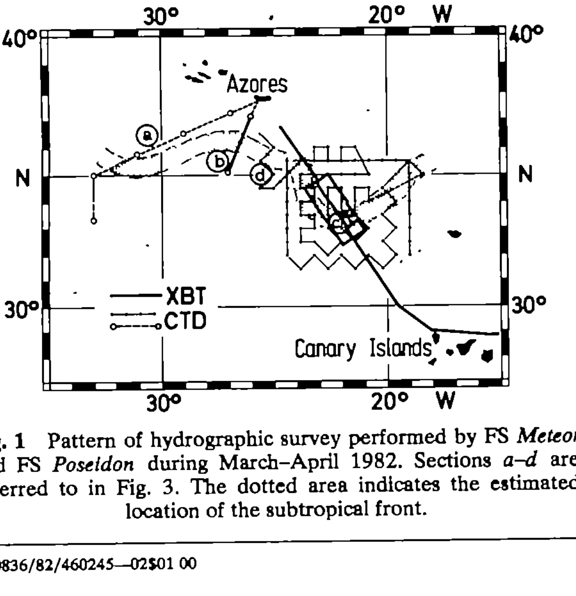

Fig. 1 Pattern of hydrographic survey performed by FS *Meteor* and FS *Poseidon* during March–April 1982. Sections *a–d* are referred to in Fig. 3. The dotted area indicates the estimated location of the subtropical front.

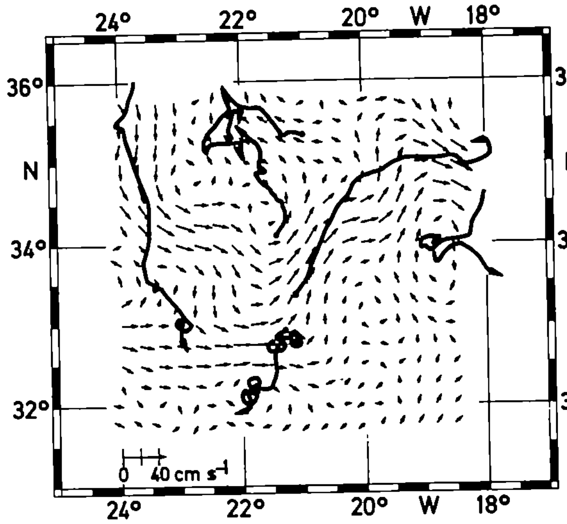

Fig. 2 Estimated geostrophic surface velocity relative to 1,500 dbar and paths of satellite-tracked drift buoys with drogue at 100 m depth. Map determined from objective analysis of geostrophic surface velocity relative to 1,500 dbar using a non-isotropic gaussian covariance function with zonal and meridional correlation scale of 100 and 65 km. Trajectories of satellite drift buoys obtained from daily fixes during FS *Poseidon* hydrographic observations.

These early data led to an easterly flow in the region where Ekman transports calculated from Bunker's[10] wind data (H.-J. Isemer, personal communication) result in an Ekman convergence zone approximately along 35° N, with a seasonal meridional shift of ±3° latitude. These results on the gyre circulation and the Ekman convergence suggest a connection between the current branching from the North Atlantic Current system towards the Azores and the current related to the subtropical front in the eastern North Atlantic.

Within the framework of the Warmwassersphäre research programme at Kiel University several cruises were performed in the tropical, subtropical and moderate latitude basins of the eastern North Atlantic. Indications of frontal variability were found to exist persistently in the region between 30 and 38° N, and subsequently observational programmes were designed for 1982 cruises with the aim of resolving mesoscale features of the frontal region south and east of the Azores (Fig. 1). FS *Meteor* in March/April occupied several XBT and CTD sections including a XBT box pattern between the Canary Islands and the Azores in the northern Canaries Basin and also south-west of the Azores close to Mid-Atlantic Ridge. FS *Poseidon* in April covered 82 CTD stations 30 nautical miles apart in a box pattern between the Azores and the Canary Islands. Also four satellite buoys deployed by FS *Meteor* previously were drifting in the area of the FS *Poseidon* box.

The geostrophic flow field obtained from the CTD box data is presented in Fig. 2. It reveals a current band with ~60 km width and 25 cm s^{-1} speed in its core, entering the box in the northwestern corner, turning east in the centre and leaving the area from the northeastern corner. This current band corresponds to large horizontal temperature gradients and also to salinity gradients in the upper ocean that specify a front. The related geostrophic shear reaches levels as deep as 650 m, more than is usually reported for surface fronts. The satellite drifters' tracks also shown in Fig. 2 conform with the general pattern of geostrophic currents obtained from the CTD data. Note that closed streamline patterns on both sides of the jet suggest the presence of mesoscale eddies with typical scales of 200 km.

The larger-scale spatial distribution of the front can be determined from further surface temperature data and temperature sections to the west of the CTD box (see Fig. 1). The surface temperatures displayed in Fig. 3 include the position of the front marked by the maximum horizontal gradient at the surface. The corresponding temperature sections are also shown

0028–0836/82/460245—02$01 00

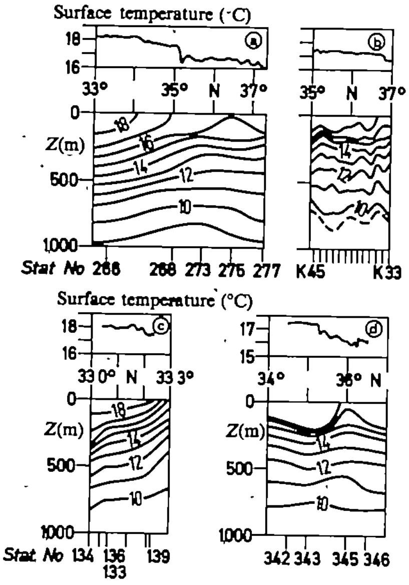

Fig. 3 Temperature obtained from sections *a–d* indicated in Fig. 1. Note the different scale in section *c*.

in Fig. 3. The front stretches zonally south of the Azores, turns to a southerly direction south-east of the Azores and in the box veers round to northerly directions. IR radiation satellite photographs confirm the existence of a continuous temperature gradient band in this general pattern (G. Hardtke, personal communication). Time variability of the front on time scales of the order of 1 month can be deduced from current meter moorings in the area. This will be discussed elsewhere.

The long-term persistence of the front can be tested by inspecting data from three different cruises: RRS *Discovery*, January 1981[11,12], FS *Meteor*, April 1981, and FS *Poseidon*, April 1982. The density at 250 m depth obtained in sections crossing the area under discussion is presented in Fig. 4. The horizontal density gradient related to the front is found at similar positions in all three sections. The observed surface front obviously separates regions with a permanent thermohaline mixed layer and subtropical thermocline from regions with seasonal thermocline formation, winter convection and advection of North Atlantic Current water masses. We suggest that the subtropical front found here corresponds to a branch of the North Atlantic Current that is already indicated as a broad band in Wüst's[6] map of potential density at 200 m. This is supported by the fact that downstream volume transports in the observed baroclinic current band related to the front are of the same order of magnitude (10^7 m^3 s^{-1}) as mean meridional Sverdrup transports across this area between the Mid-Atlantic Ridge and the African coast estimated from zonal hydrographic sections[11,12]. Transports in the narrow band at the front may thus constitute the major portion of the total long-term transport. It is also possible that the front observed here is a continuation of the frontal zone found[13] to the west of this area.

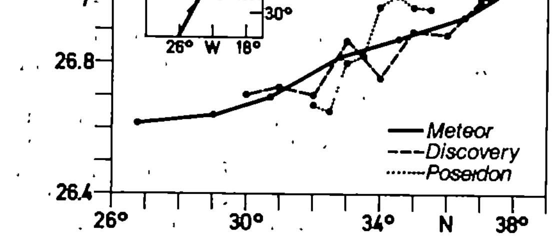

Fig. 4 Density (σ_T) at 250 m depth as function of latitude from three different cruises in the area south-east of the Azores.

The observed meandering of the front, with an even more complicated smaller-scale structure seen in IR satellite photographs, may be due to several processes. The most obvious candidates are quasi-stationary Rossby waves, which were earlier suggested[14] as the cause of wave-like patterns observed in the polar boundary of the subtropical convergence in the South Atlantic, or baroclinic instability of the jet.

We thank groups from the Institut für Meereskunde Kiel, Dr W. J. Emery from the University of British Columbia Vancouver and Dr J. Rathlev and his group from the Institut für Angewandte Physik for their efforts in data collection.

Oxygen utilization rates in North Atlantic subtropical gyre and primary production in oligotrophic systems

W. J. Jenkins

Department of Chemistry, Woods Hole Oceanographic Institution,
Woods Hole, Massachusetts 02543, USA

If the observed distribution of dissolved oxygen in deep oceans below the euphotic zone is in stationary and steady state, then it can be assumed that the *in situ* consumption of oxygen is balanced by 'ventilation', or, in other words, physical transport of oxygen from regions of higher dissolved oxygen and ultimately the sea surface. It follows, therefore, that measurement or determination of those physical transport processes, coupled with observation of the oxygen distribution will lead to an estimate of the net oxygen utilization rate (OUR). The character of such an estimate is that it is a space and time average over scales governed by the nature (space and time scales) of the transport processes, the scale of the oxygen distribution, and the climatologic nature of the system. As such, one obtains an average which is characteristically of the order of 10^8 s, 10^8 cm or more, that is large compared with scales of biological variability. I report here some new determinations of oxygen utilization rates determined by tritium dating in the North Atlantic subtropical gyre, compare them with other and previous estimates, and discuss their implications regarding primary production and nutrient cycling in an oligotrophic system.

The Beta Triangle is a triangular study area in the eastern subtropical North Atlantic whose apices are at 26.5° N × 38.5° W, 32.5° N × 30.0° W, and 22.5° N × 28.5° W. The area was chosen as a testing ground for the Beta–Spiral calculations—a geostrophic computation which yields absolute flow velocities[1]. The Triangle has sides of ~1,000 km each and is characterized by significant oxygen gradients on isopycnals. The shallow flow is of the order of 1 cm s^{-1} to the south-west.

As part of the Beta–Spiral study, the Triangle was intensively sampled for the transient tracers tritium (^3H) and ^3He. The strategy was to use the observed tracer distributions to obtain an independent estimate of velocity field for comparison with the dynamical (Beta–Spiral) calculations. The preliminary results agree well (work in preparation) which lends credence to the results obtained using the tracers alone.

Tracer samples were obtained on three density levels ($\sigma_\theta =$ 26.45, 26.6, 26.8‰) at 15 stations on the perimeter of the Triangle and three stations in the interior. The tritium and ^3He were measured using the mass spectrometric method[2] to 1.0% (±0.04 TU) and 1.6‰ respectively, and the ^3H–^3He age computed as

$$T = 1/\lambda \ln\left(1+\frac{[^3He]}{[^3H]}\right) \qquad (1)$$

where $1/\lambda$ is the tritium mean life, here taken as 17.96 yr. Age non-linearity is not significant on the time scales observed here[2], particularly because the tritium field is homogeneous on these levels.

The data are summarized in Fig. 1, where the regression lines obtained yield the OUR for each surface. Note that the ^3H–^3He age range encompassed by each surface is of the order of several years; that is, an order of magnitude greater than measurement uncertainty. The same holds true for the oxygen range. The least squares regression parameters are summarized in Table 1 with the uncertainties (1 s.d.) of the estimates. It is encouraging that the intercepts, the zero age AOU values, are not significantly different from zero.

Implicit in this analysis is the assumption that lateral mixing is small. Armi and Stommel[3] have analysed the salinity fields in the Triangle and their results confirm this hypothesis. Furthermore, lateral mixing will, in the first order, be transparent as it will reduce not only the ^3H–^3He age gradients, but also the oxygen gradients. At least for the present analysis, therefore, it is reasonable to adopt the statistical uncertainties in the regression slopes as representative of the accuracy of this OUR determination. These are reflected in the error bars for these OUR measurements in Fig. 2.

Riley[4] used a geostrophically 'calibrated' three-dimensional advection diffusion calculation for the North Atlantic to obtain estimates of OUR for various surfaces. Inasmuch as uncertainty in the reference level for the geostrophic calculations produces a barotropic uncertainty no more than the order of a few millimetres per second, the shallow estimates are probably accurate to within 10–20%, whereas deeper estimates may be more suspect. Those results, plotted on a depth scale, are compared with the present results in Fig. 2.

Figure 2 also shows results obtained from ^3H–^3He dating[5] and from a ^3H–^3He calibrated lateral mixing model[2], both in the Sargasso Sea. These calculations differ from the Beta Triangle OUR values in that they are 'end-point' determinations—they reference to saturation values for oxygen at zero ^3H–^3He ages. The Beta Triangle OUR, on the other hand, represents a gradient determination.

The results all show a remarkable consistency for depths above 1 km, particularly in light of the differences in the techniques. Although the results diverge below 1 km, this can be explained on the basis of the barotropic uncertainty in Riley's computations[2]. Irrespective of this disparity, the bulk of the water column oxygen utilization occurs above 1 km where the results agree.

The oxygen utilization rates shown in Fig. 2 below the euphotic zone (~100 m in depth) may be integrated to yield the net oxygen consumed in the water column. The simplest approach is to use a log linear consumption rate–depth dependence, the best fit being

$$\ln \mathrm{OUR} = -(0.68 \pm 0.17) - (0.00295 \pm 0.00027)z \qquad (2)$$

where OUR is the oxygen utilization rate in ml per l per yr and z is the depth in m (positive downward). Integrating between 100 m and infinity, one obtains 5.7 mol oxygen consumed m^{-2} yr^{-1}. In order that the consumption of this oxygen be supported, the water column below the euphotic zone must be supplied with ~4.5 mol C m^{-2} yr^{-1}, or 55 ± 5 gC m^{-2} yr^{-1}.

This corresponds to a remarkably large flux of carbon out of the euphotic zone. It is double the currently accepted mean oligotrophic primary production rate[6], and if the level of recycling of primary production carbon approaches 80–90% as recently suggested[7,8], then the actual amount of carbon fixed at the ocean surface in the subtropical gyre may be several hundred grammes of C m^{-2} yr^{-1}. This result, therefore, may conflict with commonly accepted ^{14}C assimilation rate measurements of net surface primary production.

Schulenberger and Reid[9] used observations of shallow subsurface oxygen maxima to estimate minimum surface oxygen production and hence carbon fixation rates. Their results showed carbon fixation rates 2 to 7 times higher than ^{14}C assimilation estimates, and because that they could not account for what may be substantial photosynthetic oxygen loss to the atmosphere, represented a conservative lower limit to the disagreement between the techniques.

Primary production estimates have been based on the small bottle, long incubation technique of ^{14}C-bicarbonate assimilation. This technique has recently been criticized by workers[9–11] who have suggested that it may substantially underestimate the true carbon uptake. Whereas the ^{14}C uptake technique may suffer from statistical sampling problems (due to space and time variabilities) and the possible difficulty of perturbing the systems being measured, the water mass tracer techniques achieve realistic space–time averages and are true *in situ* determinations. The results described here represent time averages extending from years to decades (in the deeper waters) and space averages from a few hundred kilometres to the whole subtropical gyre. The Schulenberger and Reid results[9] yield time averages of a few months and space averages probably of the order of a few hundred kilometres. Clearly the water mass approach, which is based on a wide variety of techniques—transient tracers, dynamical calculations and seasonal photosynthetic oxygen cycles—presents a compelling argument for either substantially higher surface production than depicted by the ^{14}C assimilation techniques, or less efficient recycling within the euphotic zone. Whereas the results presented here only constrain the flux out of the euphotic zone, other results[9–11] suggest that at least part of the problem lies with the ^{14}C techniques.

The proposed large surface productivity requires a correspondingly greater supply of nutrients (NO_3 and PO_4). The requirement is that the flux of carbon from the euphotic zone be balanced in the appropriate stoichiometric proportions by a return of nitrogen and phosphorus from the deep water. Using a transient tracer calibrated lateral transport model[2], one can

Table 1 AOU–^3H–^3He age regression results

Surface (σ_θ in ‰)	Approximate depth (m)	Intercept (ml per l)	Slope (OUR) (ml per l per yr)
26.45	200	0.10±0.08	0.173±0.029
26.60	300	−0.10±0.11	0.196±0.025
26.80	400	0.12±0.18	0.169±0.028

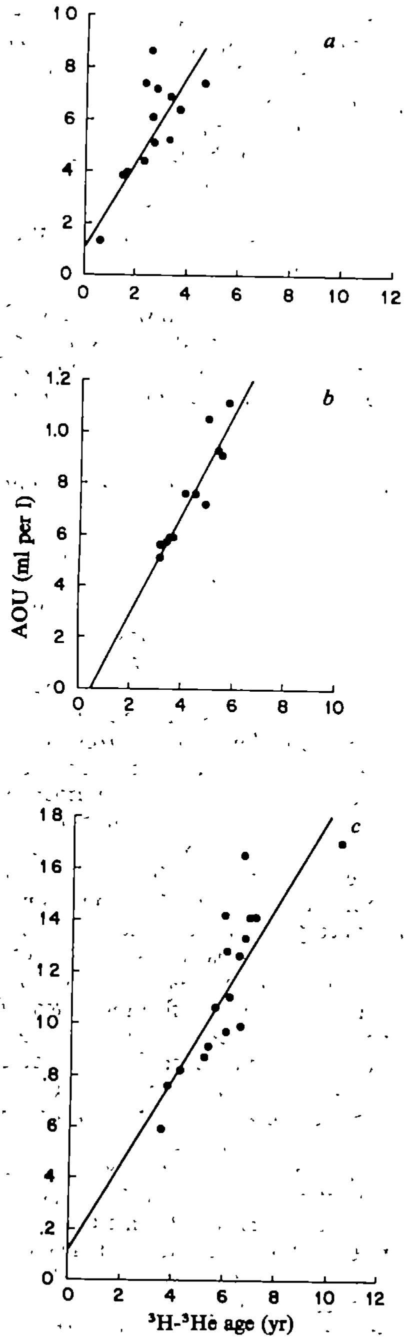

Fig. 1 AOU plotted against ^{3}H–^{3}He age for three density surfaces *a*, $\sigma_\theta = 26.45$; *b*, $\sigma_\theta = 26.60$; *c*, $\sigma_\theta = 26.80$ in the Beta Triangle (see text).

estimate the reflux of for example, nitrate to the surface by the relation

$$F(\mathrm{NO_3}) = \int_{100}^{D} \frac{C(\mathrm{NO_3})}{T}\,\mathrm{d}z \qquad (3)$$

where $F(\mathrm{NO_3})$ is the flux of nitrate, $C(\mathrm{NO_3})$ is the depth-dependent water column nitrate concentration and T is the depth-dependent residence time[2]. The integration is from some depth D to the base of the euphotic zone (here assumed to be 100 m).

Using GEOSECS station 121 (35°59′ N, 67°59′ W) nitrate data[12] as a typical Sargasso Sea nitrate profile and integrating as in equation (3), one obtains a nitrate flux of 0.7 mol $\mathrm{NO_3}$ $\mathrm{m^{-2}\,yr^{-1}}$ which almost perfectly matches the requirements of the carbon flux reported here. A similar calculation may be performed for phosphate, but note that inasmuch as the Redfield ratios for AOU : N : P are observed quantities, and that the nutrient fluxes are 'calibrated' using the same tracer model as the OUR estimates, the nutrient fluxes must *a priori* yield a result consistent with the carbon flux.

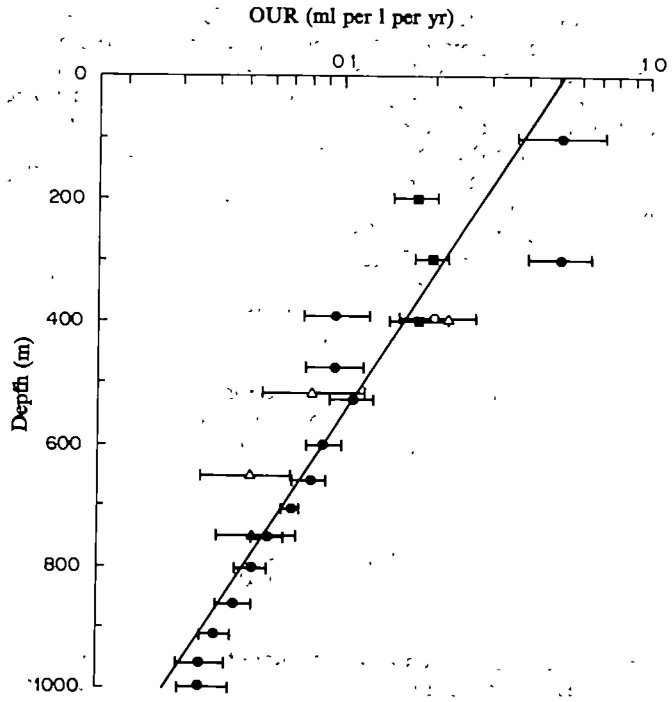

Fig. 2 Oxygen utilization rates plotted against depth from ^{3}H–^{3}He dating (■, ○), a geostrophically calibrated three-dimensional advection–diffusion model (△) and a ^{3}H, ^{3}He calibrated isopycnal mixing model (●).

On the basis of large scale tracer distributions, dynamical balance and subsurface seasonal photosynthetic oxygen maxima, I conclude that surface fixation of carbon in the subtropical open ocean is many times greater than deduced from ^{14}C assimilation techniques. A downwards carbon flux from the euphotic zone in excess of 50 g C $\mathrm{m^{-2}\,yr^{-1}}$ is deduced from water column OURs. These essentially independent determinations, based on different approaches are all characterized by large space and time scale averaging. This, coupled with the fact that they are independent yet yield the same results lends credence to the high rates predicted. It is therefore becoming increasingly clear that the ^{14}C assimilation techniques are in error and that oceanic 'oligotrophic' primary production is considerably higher than previously thought.

I thank J. Goldman for encouragement, information and valuable suggestions, and J. Steele for critical comments. The Beta Triangle ^{3}H–^{3}He samples were collected by Larry Armi and Henry Stommel. This work was supported by NSF grant OCE-79-19815. This is Woods Hole Oceanographic Institution contribution no. 5170.

Amino acid evidence for Devensian ice, west Gower, South Wales

S. Campbell*, J. T. Andrews† & R. A. Shakesby*

* Department of Geography, University College of Swansea, Singleton Park, Swansea SA2 8PP, UK
† INSTAAR and Department of Geological Sciences, University of Colorado, Boulder, Colorado 80309, USA

Complete inundation of South Wales by ice during the penultimate (Wolstonian?) glaciation has been widely suggested[1-3]. Although it is generally agreed that the last glaciation was less extensive than the preceding one[4-6], there has been controversy concerning its limits, stemming mainly from the lack of clear geomorphological evidence and the dearth of datable material[7-9]. ^{14}C dates from the shelly till in Pembrokeshire were first thought to indicate an extension of last glaciation ice into the area[10], but serious doubts were subsequently raised about the reliability of finite dates on shells of this age range[11,12]. We present here results of amino acid analysis of shells from recently exposed till and from underlying raised beach remnants at Broughton Bay, west Gower. Total D *allo* : L *iso* ratios from the raised beach are consistent with analyses on shells from comparative beach remnants elsewhere in south-west Britain[7,13-15]. Shells of 21 identifiable littoral species extracted from the till suggest inshore marine conditions similar to those at present. Amino acid ratios from *Littorina* spp. provide firm evidence for the encroachment of Devensian ice on to Gower, approximately to the limit suggested by Bowen[7] (Fig. 1*a*).

Absence of unequivocal dated evidence from elsewhere in South Wales has focused attention on coastal sections of Gower, where exposures of glacial and periglacial drifts overlying prominent raised beach fragments, have been regarded as key sites for establishing the Pleistocene chronology of the area[1,11]. Both Hoxnian[8] and Ipswichian ages have been suggested for these fragments; however, a composite origin within the Ipswichian has been established[7,14,16]. Bowen's limit for Devensian ice across Gower (Fig. 1*a*) rests largely on the acceptance that drifts containing erratics exposed in coastal sections east of Langland Bay and near Whitford Point are *in situ* Devensian glacial deposits, whereas exposures of erratic-bearing drifts associated with the local head west of Langland Bay along the south coast are regarded as redistributed Wolstonian glacial material[1]. A conjectural interglacial soil on Worm's Head[17] and soils considered to be in a colluviated state along the south coast west of Langland Bay[1] have also been cited as evidence in support of this ice limit. Other workers, however, have considered that Gower remained largely ice-free during the last glaciation[4,5] (Fig. 1*a*).

Recent coastal erosion at Broughton Bay (Fig. 1*b*) (SS: 419931) has revealed up to 5 m of a compact *in situ* diamicton containing broken and complete shells near its base (Fig. 1*c*). We interpret this sediment as a till; it is overlain by solifluction deposits and colluvium. The exposures run ~300 m eastwards from Twlc Point, where the till overlies fragmented raised beach sediments that contain a shell fauna comprising mainly *Littorina littoralis*. Fabric analysis (Fig. 1*b*) and erratic content of the till both point to a northerly (Welsh) provenance. Various marine shell species were removed from the basal 2 m of the till. The collection (Table 1) included 21 identifiable species, all of which live in the area now, except for *Arca lactea* and *Acanthocardia tuberculata*. These last two species are rare today and suggest slightly warmer conditions (N. McMillan, personal communication).

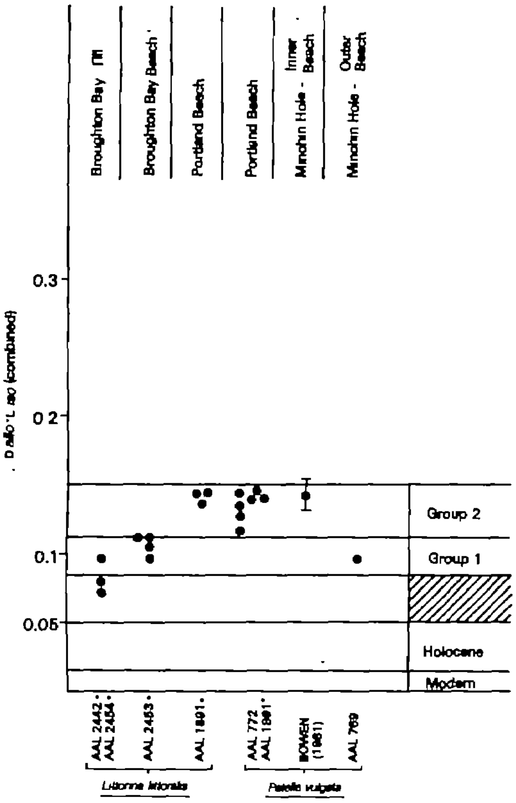

Fig. 2 Comparative amino acid ratios for south-west Britain (after ref. 14). * New data from the present results.

Littorina littoralis shells from the till and raised beach were prepared for amino acid analysis by the method described elsewhere[14,15], and the results are shown in Table 2. The tight clustering of the total ratios for these *Littorina* shells from the raised beach (AAL-2453) of 0.107±0.014 suggests strongly a non-mixed population. These values are lower than those obtained for *L. littoralis* from the raised beach at Portland (0.137±0.005) ($n = 3$, AAL-1891, A, B, C). (The ratios reported from Broughton Bay have been recalibrated against other samples run earlier. This procedure was necessary because detailed analysis involving many tens of runs indicated that the preparation method used for about 9 months in 1981 gave ratios that were consistently too high[18].) *Patella vulgata* from the same unit at Portland, collected by Briggs, gave total D *allo* : L *iso* ratios of 0.13±0.005 (AAL-1891, D, E, F). Comparable results derived from the 8 m beach on Jersey have been related to an absolute U-series date of $121\pm^{14}_{12}$kyr BP (ref. 13), and an average amino acid ratio of 0.14 for *P. vulgata* from the inner raised beach at Minchin Hole gives further indication of comparable relative ages for some of the raised beach fragments in south-west Britain[7]. The Broughton Bay ratios fall into group 1 of Andrews *et al.* (Fig. 2) and are thus probably younger than $121\pm^{14}_{12}$kyr BP.

The validity of these correlations rests principally on the acceptance of a comparable inter-site temperature history and of a similar kinetic relationship between the species *P. vulgata* and *L. littoralis*. The present mean annual temperatures of 10.9 °C at Gower (Swansea), 10.8 °C at Portland and 11.9 °C at Jersey (St Helier) are reasonably close. However, whether temperatures at these sites have consistently remained as close throughout the past 100 kyr, particularly during cold phases, is less certain. Taxon-dependent racemization differences are not judged to be a factor here on the basis of the close comparison between *L. littoralis* and *P. vulgata* (Fig. 2). Consequently, a correlation of the Broughton Bay raised beach with other beach fragments broadly regarded as Ipswichian (stage 5) in south-west Britain seems justified.

Table 2 Amino acid racemization results

Sample		Species	D *allo* : L *iso* (combined)	
AAL-2453	a	*Littorina littoralis*	0.115	Beach
	b	*Littorina littoralis*	0.107	
	c	*Littorina littoralis*	0.098	
	d	*Littorina littoralis*	0.115	
AAL-2442	a	*Littorina littoralis*	0.082	Till
	b	*Littorina littoralis*	0.073	
AAL-2454	a	*Littorina littoralis*	0.098	
Average D *allo* : L *iso* (combined):				
Littorina littoralis (Broughton Bay beach)			0.107±0.014	
Littorina littoralis (Broughton Bay till)			0.082±0.022	
Littorina littoralis (Portland beach)			0.137±0.005	
Patella vulgata (Portland beach)			0.130±0.005	

Littorina littoralis from the till yielded a slightly lower mean total D *allo* : L *iso* value of 0.082±0.022 than that from the raised beach (0.107±0.014) but still showed a relatively unmixed population. Hence, whereas the raised beach at Broughton Bay can be correlated by amino acid ratios with the outer beach at Minchin Hole, ratios for the till are on average slightly younger, although the ratios overlap at the 95% confidence level. A maximum relative age for the ice advance would be indicated by the ratio of the least racemized *L. littoralis* shell, namely 0.073±0.007.

The amino acid evidence therefore indicates that the shells in the till date from no earlier than the Ipswichian (~$121\pm^{14}_{12}$kyr BP (ref. 13)), and that some shells post-date the raised beach event at Broughton Bay. This evidence strongly suggests, therefore, that it must have been ice of Devensian age, and no older, which moving southwards across the eastern part of Carmarthen Bay, incorporated shell litter that had accumulated during the preceding interglacial. The fabric and erratic content of the shelly till deposited at Broughton Bay support this interpretation.

The point at which the Broughton Bay shelly till was deposited within the Devensian period cannot be resolved easily. The amino acid ratios themselves indicate the shell fauna is most probably early Devensian in age. This, however, only establishes a maximum age for a glacial event which incorporated the shells in the diamicton. On the other hand, stratigraphical[1,11] and palynological[19,20] data from the local area, point strongly to last glaciation deposits in the vicinity being late Devensian in age. The lack of amino acid ratios extending into middle or late Devensian times does not necessarily contradict the latter view; with sea level falling at the close of the Ipswichian, much of Carmarthen Bay would have remained as dry land during this period, preventing further accumulation of younger marine shells. Thus whilst the amino acid ratios presented above do not allow precise dating of the Broughton Bay shelly till within the Devensian period, they do demonstrate the encroachment of Devensian ice sheets on to west Gower. Furthermore, our results demonstrate the potential of amino acid ratios for resolving certain chronological aspects of the various shelly drifts of the UK and elsewhere[21].

We thank the University of Colorado Council for Research and Creative Work for financing the amino acid ratios, Dr N. McMillan for shell identification, Mr M. Bristow for drawing attention to the Broughton Bay sections and Dr J. A. Matthews, Dr C. Harris and Professor N. Stephens for comments. S.C. is financed by a University of Wales award. Dr W. Briggs, University of Colorado, donated the *Patella* and *Littorina* shells from the Portland site. They were collected in 1977.

Comparison between the hot spot and geomagnetic field reference frames

C. G. A. Harrison & T. Lindh

Rosenstiel School of Marine and Atmospheric Science,
University of Miami, Miami, Florida 33149, USA

Hot spots are located on the Earth's surface and are caused by hot plumes of upwelling mantle material. They manifest themselves by volcanic activity which changes its location in response to the movement of the lithosphere over the mantle plume. It has been suggested[1–3] that hot spots are relatively stationary with respect to each other, and also that they represent a frame of reference with which to measure the absolute movement of the lithospheric plates over the surface of the Earth. Another frame of reference can be partially defined by the position of the mean magnetic dipole field of the Earth. As the dipolar field is believed to be closely related to the spin axis, this frame of reference automatically gives information about the palaeolatitude and orientation of the lithospheric plates. But since the position of the ancient dipole field of the Earth does not give any information about palaeolongitude, and since in many cases the definition of the field is relatively poor due to less than adequate rock collections during the time of interest, hot spot reference frames have been favoured by many people. We now report a comparison of the two frames of reference and show that over the past 200 Myr there has been relative movement between the two frames of reference of about 20°, and that this motion has not been constant with time.

We have developed a new method for calculating palaeomagnetic poles for individual continents[4]. As the relative positions of most continents are moderately well known during the Neozoic, it is also possible to use the palaeomagnetic information from one continent to define with greater accuracy the palaeomagnetic pole for another continent. Data for North America are shown in Table 1. The apparent polar wandering (APW) path shown on the left is that generated solely from North American palaeomagnetic data[4]. The APW path on the right has been generated using data from five continents (North America, South America, Africa, Europe and Australia) and using the relative rotation parameters given by Barron *et al.*[5] to express the palaeomagnetic poles of all continents in the North America frame of reference. The method of analysis of the rotated poles is similar to that described in ref. 4. There are two important results obtained by using the world data to define a North American polar wandering path.

First, the accuracy with which the pole may be defined can be significantly increased by using data from the other continents as well. The average value of α_{95} (the radius of the 95% circle of confidence around the mean) has decreased from 5.7° to 3.5° by using the data from Australia, South America, Europe and Africa in addition to those from North America, to define the North American APW path. Second, the two polar paths can differ by almost 10°, which occurs during the Upper Cretaceous and the Middle and Upper Jurassic. The ratio between the average values of α_{95} using just the North American data and using the data from all five continents is 0.61. If the relative positions of the continents were perfectly well known during the time interval considered, there should have been a reduction in the value of α_{95} equivalent to the square root of the ratio of information contained in the North American data to the information contained in the data from all five continents, which is 0.53. Thus, although the relative position information for the continents is not perfect, the reduction in α_{95} approaches that which would be expected considering the added information content and an assumption that the relative position information is correct. This is obviously not true in some cases; for instance the 200 Myr information shows no reduction in α_{95} whereas it should have been reduced from 2.8° to 1.6° if it were purely dependent on the amount of information used.

We compare the finite motions predicted by hot spots, and APW paths back to 200 Myr. Morgan[1] has defined the motions of the major continental plates with respect to a hot spot reference frame for this time interval. It is possible to use these data to generate pole positions on the assumption that the hot spot reference frame is fixed with respect to the geomagnetic field. We can then compare these calculated polar positions with those generated using palaeomagnetic data to see if the assumption holds true. We show three sets of results. The first set is given in Table 2 and compares the two polar wandering paths for Europe. The last column of this table shows the angular deviation between the two sets of results. Deviations increase from the present back to 50 Myr at which time there is a reduction in the deviation. From 70 to 180 Myr the deviation again increases and reaches a value of 17.6°.

When we generate polar wandering information for any continent we use relative position information which is different from that used by Morgan. Therefore, we obtain different results for different continents. This set of results (which

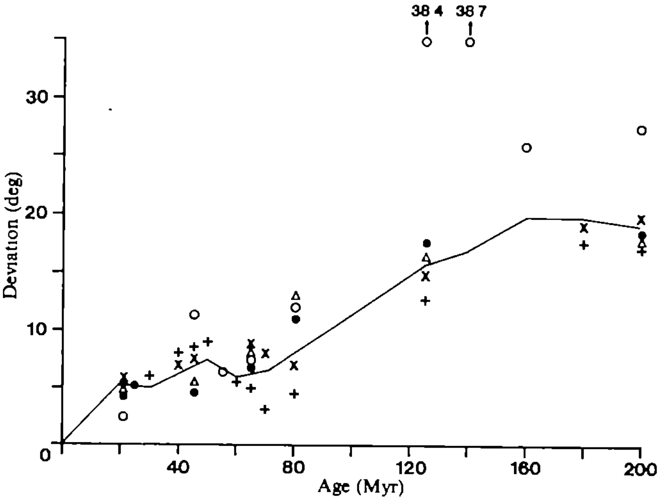

Fig. 1 Deviations between APW paths predicted using a hot spot reference frame and those using palaeomagnetic data. Average			5.7			3.5	

includes the values for the last column in Table 2) is presented in Fig. 1, in which the scatter for any one age reflects the fact that our relative position information is different from that given by Morgan. In particular, the very large deviations seen for Australia between 125 and 140 Myr are due to the fact that Morgan's position for Australia during these times is such that the APW path for Australia would predict poles very close to the present pole, whereas in our reconstruction Australia lies considerably further south and is rotated compared with its present position. It should be possible to use palaeomagnetic data to determine which of these reconstructions is better, but unfortunately, there are almost no data for Australia during this time interval[6]. The points plotted in Fig. 1 suggest an increase in the deviation between the present and about 40 Myr before which there is a suggestion of a slight decrease in the deviation. The deviation increases between about 70 and 180 Myr. The close grouping of the data from the four continents surrounding the Atlantic Ocean at 200 Myr is because our reconstruction of Pangaea[7] is very similar to that of Morgan[1], the only major difference relevant to this study being in the relative position of Australia.

Duncan[8] has also produced absolute motion parameters of the southern continents with respect to a hot spot frame of reference, back to 100 Myr ago. Deviations calculated using his data fall within the scatter of the points shown in Fig. 1.

Table 2 Comparison between observed APW path for Europe and that predicted by motion of Europe w.r.t. the hot spots

	Predicted APW position		Observed APW position*

* Observed APW position calculated using data from all five continents plus the relative position information.

We have also generated another global polar wandering path using the same palaeomagnetic data but using the relative position information given by Morgan[1]. The polar wandering path for North America is in fact very similar to that given in Table 1. Deviations between the two average 2.5°, the largest being 6.2° at a time of 160 Myr. The inaccuracy for each pole is marginally greater for Morgan's reconstruction data (mean $\alpha_{95} = 3.6°$). Comparison between this polar path and the hot spot data need be done only once, since the same relative position information was used for both sets of data. The deviation between the two is shown by the line in Fig. 1.

The average motion between the two frames of reference during the 200 Myr interval of observations is about 19°, representing a speed of motion of 10.6 mm yr^{-1}. The relative speed of motion was faster during the period 60–160 Myr, being about 15.6 mm yr^{-1}. The motion established by the point at 21 Myr gives a speed of motion between the two reference frames of 28.0 mm yr^{-1}, but the error in this number is much greater because it is based on a smaller deviation.

A word must be said about errors, Presumably, the hot spot traces, being marked by geological features, are accurately placed to within 1°. There may, however, be errors associated with assigning ages to the traces. Because most of the hot spots used by Morgan are within continental regions at the start of his reconstruction, the ages should be much better known than for oceanic hot spot traces. A typical radiometric age has an error of 3% of the total age, or 6 Myr in the case of the 200 Myr hot spot traces. At a motion of 30 km Myr^{-1}, this age error is equivalent to an angular error of about 1.6°. Thus a possible hot spot error might be given by the square root of the sum of the squares of 1.6 and 1, or 1.9°. The polar error could likewise be considered to be made up of errors due to the palaeomagnetism (average of 3.5°, Table 1) and errors due to plate reconstruction (taken as the mean polar difference between Morgan's relative position data and ours of 2.5°) giving a total palaeomagnetic polar error of 4.3°. The total possible error in the deviation will be in the region of 4.7°, and so the observed deviation of over 19° observed at 200 Myr represents a real effect. Possible errors in the reconstruction of Gondwanaland will have little effect on the overall result since only 7% of the palaeomagnetic data come from Australia. The remaining 93% of the data come from Europe, North and South America, and Africa, whose relative positions are well known apart from minor differences between various models.

Morgan[1] also showed that there was relative motion between his hot spot reference frame and the geomagnetic field. But the greater number of palaeomagnetic data that we have used has described the effect more accurately. The details of the relative motion revealed by this study also differ from those suggested by Morgan. This relative motion between the hot spot and the geomagnetic field reference frames is considerably greater than the relative motions which take place between the hot spots which are about 5° in 200 Myr according to Morgan. If this supposition is correct, it is necessary for the layer within the mantle at which the hot spots are generated to be drifting slowly with respect to the spin axis of the Earth, to which we assume the geomagnetic field is fixed.

Thermal convection in magmas generated by hot-plate heating

Robert P. Lowell

School of Geophysical Sciences, Georgia Institute of Technology, Atlanta, Georgia 30332, USA

A condition is derived here for the onset of thermal convection in a layer of silicate partial melt that is generated by suddenly and continuously supplying an anomalous heat flux or by maintaining an anomalous high temperature on a plane at some depth within the Earth so that the overlying material is heated to greater-than-solidus temperatures. The results show that for highly fluid basaltic magmas convection may begin in a layer only 10-m thick, whereas for viscous rhyolitic magmas, at least a 10-km thick layer is required. The fact that thermal convection may occur within such a thin layer of basaltic partial melt may partially explain the homogeneity of large volumes of flood basalts that occur. Since convection within rhyolitic partial melts is unlikely, homogeneous rhyolites must be the result of mixing in magma chambers.

Although the hot-plate model is an oversimplification of the process of melt generation within the Earth, it may be relevant to the generation of rhyolite magmas near subduction zones, where mafic intrusions may supply heat to melt partially the overlying crust. Hodge[1] has suggested such a model for the generation of granitic batholiths. Hodge's calculations show, for example, that the heat transferred from a cooling mafic sill 4 km thick, initially at 1,200 °C, that is emplaced in country rock initially at 500 °C and which has a melting temperature of 700 °C, is sufficient to generate nearly a 1-km thick layer of partial melt of granitic composition within 40,000 yr. Hodge did not discuss whether convection could occur within the partial melt layer, however.

The nature of the heat source that would act as a hot-plate for the generation of basaltic magma in the mantle cannot be specified with certainty. Yoder[2] has suggested that a peridotite diapir that is depleted of its basaltic constituents or that an inflection in the geotherm might provide the required heat flux.

Although the hot-plate model is an approximation to natural mechanisms of magma generation, the model is a useful first step towards an understanding of magma genesis and transport. Moreover, the hot-plate process is amenable to laboratory investigation. Yoder[3] is carrying out experiments on the onset of convection in a two-component silicate partial melt heated from below. The present calculation may provide a useful tie between theory and experiment.

A simplified schematic of the hot-plate model is shown in Fig. 1. In reality the partial melt region is very complicated. In a multi-component system, the partial melt fraction and its compositions are a function of temperature, pressure, and bulk composition of the source rocks; consequently, the physical parameters of the system will vary as a function of height in the partial melt layer. It is not possible to take into account changes in density, specific heat, thermal conductivity, viscosity, permeability, and so on; so the conditions for the onset of thermal convection in a growing layer of silicate partial melt will be determined by assuming a system with uniform properties and by assuming melting at a fixed temperature.

Observations on the partial melting of silicate rocks in laboratory experiments have shown that when partial melts form, the liquid coats the grain boundaries of the remaining solid matrix[4,5]. The melt thus provides porosity and permeability within the partial melt, and the magma may flow along grain boundaries. The dynamics of the magma will be assumed to be governed by Darcy's law for flow in a porous medium[6–9].

The problem is to determine the condition for the onset of convection in a fluid-saturated porous medium heated from below, where the height of the layer grows with time in a manner determined by the rate of advance of solidus boundary. When the layer reaches a certain critical thickness, the conduction regime will become unstable and thermal convection will be set up. The condition for the onset of convection is expressed by a dimensionless parameter termed the Rayleigh number, the exact form of which depends on the boundary conditions that are applied[10]. The bounding surfaces are assumed here to be rigid and the temperature at the top is the melting temperature T_m, and at the base of the layer a fixed temperature T_1 will be maintained. With these boundary conditions, the critical Rayleigh number, R, is $4\pi^2$ (ref. 10). Thus:

$$R = \frac{\rho_t s \alpha g X(t)^2 K \langle \partial T_0/\partial x \rangle}{\lambda \nu} \geq 4\pi^2 \qquad (1)$$

where ρ_t, s, and α are the density, specific heat, and thermal expansion coefficient of the melt, respectively; g is the acceleration due to gravity; $X(t)$ the thickness of the partial melt layer; K the permeability; $\langle \partial T_0/\partial x \rangle$ the mean conductive temperature gradient maintained across the layer, λ the thermal conductivity of the solid–fluid mixture, and ν the kinematic viscosity of the melt.

The mean conductive gradient is found from a solution to the Stefan problem[11]:

$$T_0(x, t) = T_m + \Delta T\{1 - [\operatorname{erf} x/2(at)^{1/2}]/\operatorname{erf} Q\} \qquad (2)$$

where $\Delta T = T_1 - T_m$, $a = \rho_t s/\lambda$, and Q is found from the relationship

$$Q\,(\operatorname{erf} Q) \exp(Q^2) = St/\sqrt{\pi} \qquad (3)$$

where the Stefan number, St, is defined as $St = s\Delta T/\chi L$; χ is the partial melt fraction and L is latent heat of melting. The motion of the phase boundary is given by:

$$X(t) = 2Q(at)^{1/2} \qquad (4)$$

From equation (2), the mean temperature gradient is given by $\Delta T/X(t)$.

The interconnected pathways that provide the permeability within the partial melt zone are undoubtedly quite complex. Nevertheless, a reasonable approximation to the permeability can be obtained by assuming that the solid matrix is cubical with average grain diameter b, and that the melt fills the interconnected channels of width d. It is assumed that there are no isolated pockets of partial melt. The porosity, which can then be defined as the degree of partial melt, χ, is given by[8] $\chi = 3\pi d^2/4b^2$ and the permeability by[12] $K = \chi d^2/96$. Eliminating d gives $K = \chi^2 b^2/72\pi$. On substituting for K and $\langle \partial T_0/\partial x \rangle$ into equation (1) gives the condition:

$$X(t) \geq \frac{288\pi^3 a \nu s}{\alpha g \chi^3 b^2 L St} \qquad (5)$$

Yoder[3] has suggested that 30% partial melt of basaltic composition is generated at the invariant point in the eutectic-like

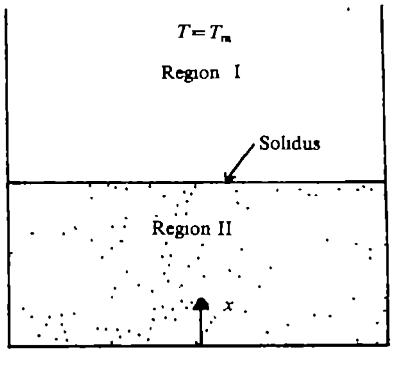

Fig. 1 Schematic of hot-plate heating model. Region I is solid at the melting temperature T_m. Region II is partially molten. A fixed temperature $T_1 > T_m$ is maintained at $x = 0$.

L	$135\ \mathrm{cal\ g^{-1}}$	See text.
St	0.2–2.0	Corresponds to a temperature range of 32–320 °C across the partial melt layer.

melting of garnet-peridotite and that the degree of partial melt increases with temperature. The degree of melt for rhyolites depends on the bulk composition, among other factors. Some rhyolite compositions, minimum melt rhyolites, form nearly 100% melt at a fixed temperature[3]. A conservative average value of $\chi = 0.3$ is assumed. The assumption of a fixed melting temperature T_m in this case means that 30% of the material melts at T_m; the rest of the material remains solid until T is considerably greater than T_1.

The latent heat of fusion is taken to be 135 cal g^{-1}, the value given by Yoder[13] for garnet-peridotite. The latent heat for rhyolite may be lower. Table 1 lists the numerical values of all the parameters used to evaluate equation (5). Substitution of the values gives

$$X(t) = 2\times10^2\ \nu/b^2St \qquad (6)$$

where ν, b are given in c.g.s. units.

Figure 2 gives a plot of equation (6) as a function of ν for a few representative values of b and St. The results show that for low viscosity, which is characteristic of basaltic magmas[14], and coarse-grained source rocks, that convection will begin in a layer of partial melt as little as 10-m thick. With smaller values of the grain size or Stefan number, or larger values of viscosity, convection will set up in a layer of 1-km thickness or less. From equations (3) and (4), the time required to generate a 1-km thick layer, when $St = 2$, is $\sim10^4$ yr, which is not an unreasonable time for a thermal event. From these calculations it would seem that convection will probably occur in the partial melt zone, and thus homogenize the magma before its leaving the source zone. This effect may partially explain the large volumes of nearly homogeneous basaltic magma that have been episodically extruded throughout geological history.

On the other hand, if the viscosity is of the order of 10^4–10^6 cm^2 s^{-1}, as may be expected for rhyolitic magmas[15], and the other parameters are held fixed as in Table 1, the thickness of the partial melt layer must exceed 10 km before convection will begin, even for the most ideal case shown in Fig. 2. For this case, the time required for generation of the layer must exceed 10^6 yr. These values of layer thickness and time required for convection to begin in a rhyolitic partial melt are not totally out of line, but they must be viewed as lower bounds. If, for example, $b = 10^{-1}$ cm or $\nu = 10^6$ cm^2 s^{-1} and the other values are held constant, $X(t) = 10^3$ km. This thickness is clearly unrealistic. It is not likely that modifications in the other parameters will alter this result much. In particular, for the porous medium model to hold χ must be ≤ 0.5. For a greater value than this, the solid matrix structure will collapse[16]. Moreover, Ahern and Turcotte[8] have shown that the matrix will begin to collapse at the bottom of the partial melt layer as a result of differential stresses, when the thickness of the layer is of the order of 100 m. Finally, if a rhyolitic partial melt layer extends to fairly shallow depths, brittle fracture may occur above the layer and the magma may escape before being mixed by convection within the source zone. Thus if rhyolitic magmas are homogenized at any time, the convection process must occur in subsidiary magma chambers.

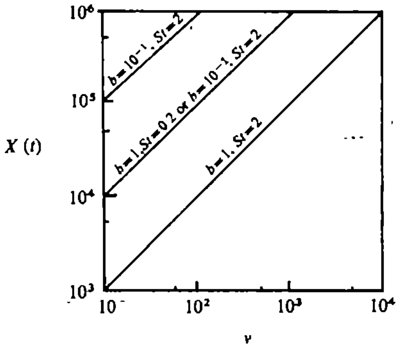

Fig. 2 Thickness $X(t)$ of partially melt layer at initiation of thermal convection as a function of viscosity ν for typical values of grain size b and Stefan number St. All dimensions are c.g.s.

Pattern of opening rates along the axis of the Mid-Atlantic Ridge

S. Le Douaran*, H. D. Needham & J. Francheteau†

Centre Océanologique de Bretagne, BP 337, 29273 Brest Cedex, France

Vine and Wilson[1], using the Vine and Matthews[2] hypothesis, were the first to try to relate the magnetic pattern over the crests of the mid-ocean ridges to the known geomagnetic time scale to determine the spreading rate over the past few million years. Many determinations of spreading rate at the axis of the ridge during Plio-Pleistocene times have been published: Le Pichon[3] and Morgan[4], for example, used spreading rates computed for the axial magnetic pattern (10 Myr: anomaly 5 of Heirtzler *et al.*[5] or for the past 5 Myr respectively) even when trying to assess the properties of instantaneous plate kinematics. Likewise in the systematic inversion of Minster *et al.*[6] anomalies 3 and 5 were generally used thus averaging plate speeds over the past 5–10 Myr. Minster and Jordan[7] sought to improve this and redetermined the spreading rates using magnetic anomalies 2 and 2′ yielding a mean averaging interval of <3 Myr. Here we examine plate behaviour over a shorter time scale in the reasonably well-surveyed axial region of the Mid-Atlantic Ridge south of the Azores. The average opening rates we obtained for this region for magnetic anomalies 1 (Brunhes), 2 and 2′ using two different geomagnetic time scales indicate that (1) there was a relative slowing down of the opening between anomalies 1 and 2 which may be of global significance; (2) the opening is compatible with a rigid plate model when it is averaged over ~2.5 Myr although for shorter averaging times (1.8 and 0.7 Myr) there is some evidence of non-rigidity of the plates. Thus different segments of the Mid-Atlantic Ridge may display an independent behaviour and, with respect to relatively short time intervals, may show departures from characteristics typically associated with slow accretion.

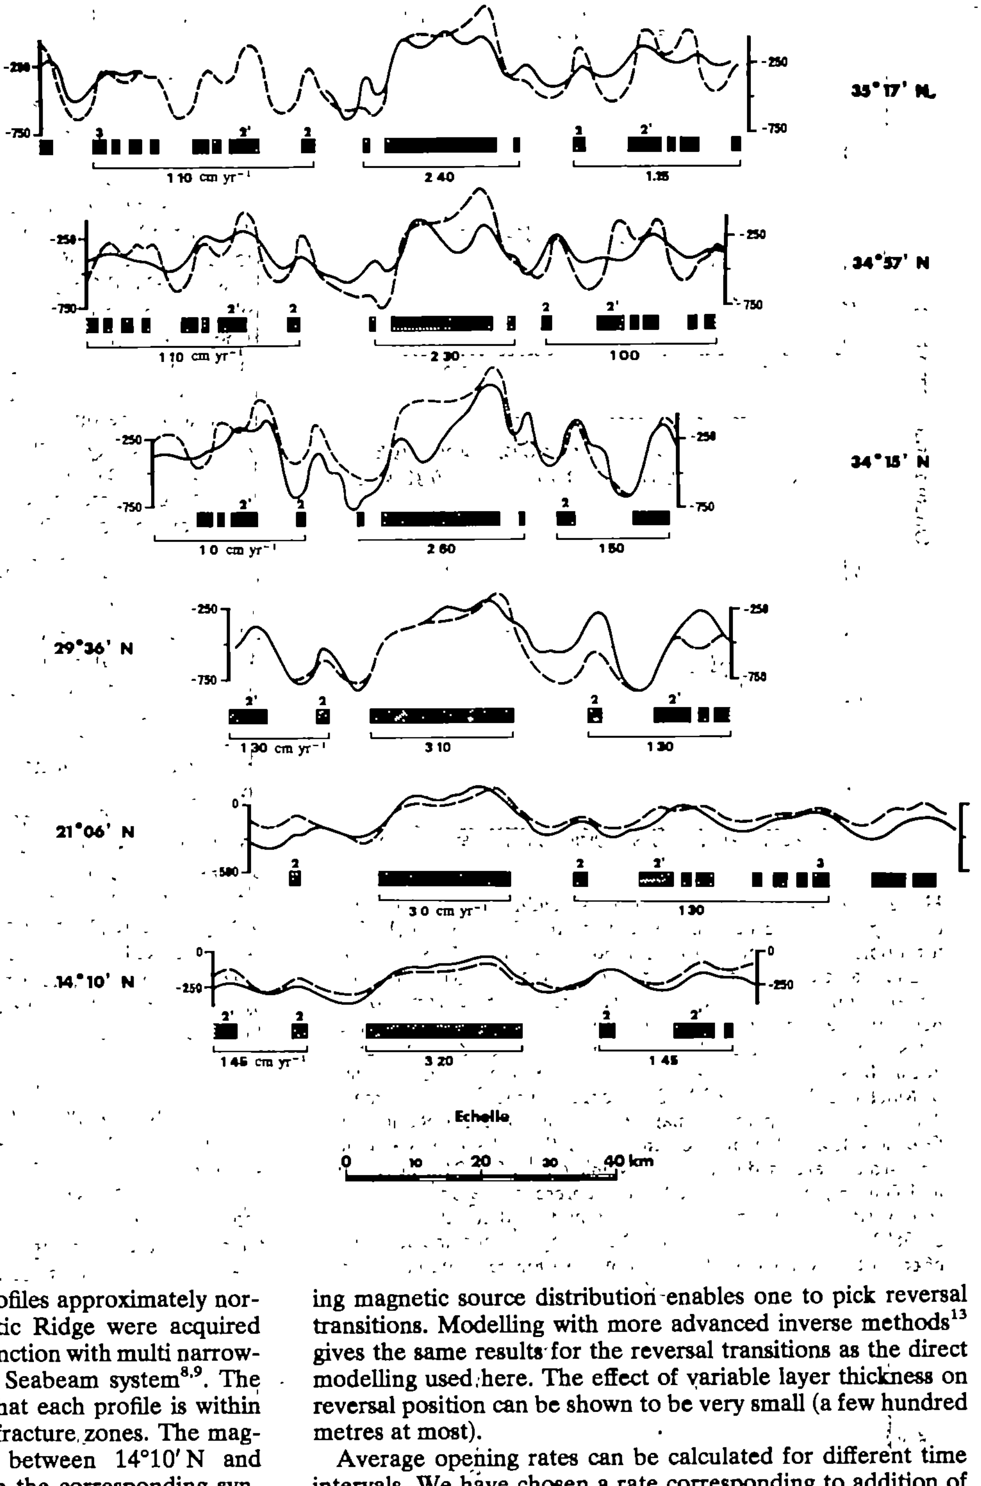

Fig. 1 Magnetic anomaly profiles along R/V *Jean Charcot* tracks during the *Vema* cruise, (solid lines) at six locations along the Mid-Atlantic Ridge south of the Azores. IGRF 75[26] has been removed from the total intensity data. The synthetic anomaly profiles (dotted lines) have been constructed piecemeal from the distribution of a uniformly magnetized horizontal magnetic source layer shown in hatched (positive polarity) and white (negative) below each profile pair. The depth to the top of the source layer is, from north to south, 2,000–2,300–2,800–3,100 and 2,500 m. This corresponds to the average ocean depth along each profile. The azimuth of the observed magnetic profiles is, from north to south, 94–101–100–107–104 and 90°. The profiles are approximately normal to the local strike of the ridge. Modelling includes the Jaramillo event for the three northern profiles. For the other profiles the axial rate applies only to the Brunhes block and Jaramillo is not resolved.

Six R/V *Jean Charcot* magnetic profiles approximately normal to the strike of the Mid-Atlantic Ridge were acquired during the 1977 *Vema* cruise in conjunction with multi narrow-beam bathymetry obtained with the Seabeam system[8,9]. The Seabeam bathymetry demonstrates that each profile is within one given crustal block bounded by fracture zones. The magnetic anomaly profiles distributed between 14°10′ N and 35°17′ N are presented in Fig. 1 with the corresponding synthetic profiles computed from the magnetic source distribution shown below each profile pair. The magnetic modelling used to compute synthetic profiles is quite simple: in each case we have assumed an horizontal magnetic source layer of uniform thickness (400 m) and intensity (0.0024 e.m.u. for all profiles except for the profile at 34°57′ N where the magnetization has been chosen as 0.02 e.m.u.). We also assume accretion to take place on a line of zero width. The uniform depth of each source layer has been chosen to match the average ocean depth along each Jean Charcot profile to take into account the varying distance to the magnetic source layer due to topographic variations along the strike of the Mid-Atlantic Ridge[10,11].

Synthetic anomaly profiles were generated at several rates using the Talwani *et al.*[12] time scale and the match between observed and synthetic anomalies was done piecemeal. Thus the synthetic profiles shown in Fig. 1 are composite. The resulting magnetic source distribution enables one to pick reversal transitions. Modelling with more advanced inverse methods[13] gives the same results for the reversal transitions as the direct modelling used here. The effect of variable layer thickness on reversal position can be shown to be very small (a few hundred metres at most).

Average opening rates can be calculated for different time intervals. We have chosen a rate corresponding to addition of new crust during the Brunhes epoch (anomaly 1; 0.69 Myr) and the average rates since the times (1.78 and 2.635 Myr) corresponding to the middle of anomalies 2 and 2′ respectively according to the time scale of Talwani *et al.*[12]. The observed opening rates averaged over these three different time intervals are plotted as a function of latitude in Fig. 2*a* which also shows the data obtained in the Famous area around 36°58′ N by Greenewalt and Taylor[14], Needham and Francheteau[15], Renard[16] and MacDonald[17]. The opening rate data are compared with the pattern of opening predicted by the inversion model of Minster and Jordan[7] for the Mid-Atlantic Ridge south of the Azores using bounds derived from the inversion model uncertainties. We compare opening rates computed along the ship's profiles which are nearly normal to the local strike of the ridge crest on the basis of Seabeam data with opening rates calculated along the direction of relative motion of the plates.

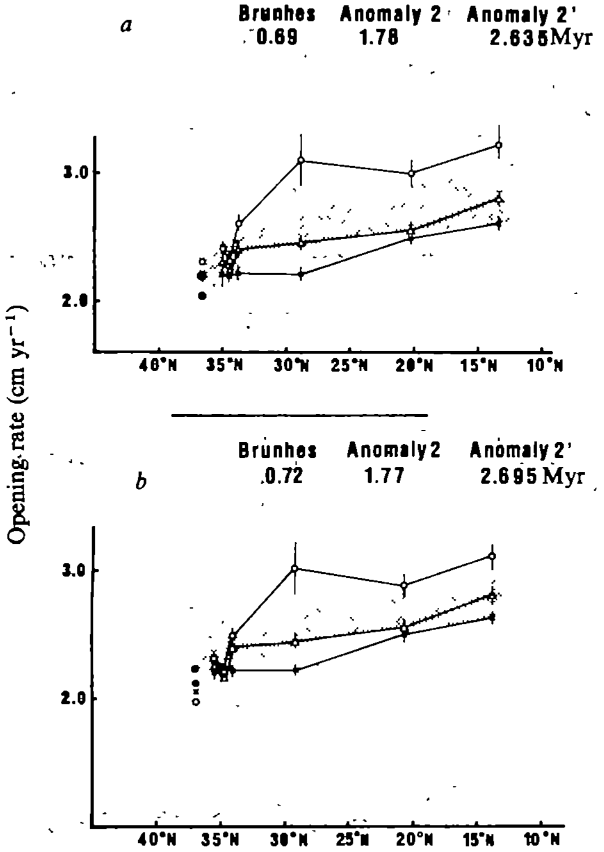

Fig. 2 Along-strike distribution of spreading rates. The total opening rates have been calculated for the Brunhes epoch (O), for a time span extending to the middle of anomaly 2 (×) and for a time span extending to the middle of anomaly 2' (△). Error bars for spreading rates have been estimated from a comparison between the synthetic model and the observed profiles. Three rates have been estimated for the latitude of the FAMOUS area at 36°58' N: a rate of 2.04 calculated for anomaly 1 and 2 times by MacDonald[17]; a rate of 2.2 for anomaly 1 time[15], up to anomaly 2 (ref. 27) and up to anomaly 3[16]; a rate of 2.3 obtained by Greenewalt and Taylor[14] for anomaly 1 time. Two geomagnetic time scales were used (Fig. 2*a*, Talwani *et al.*[12]; Fig. 2*b*, Mankinen and Dalrymple[18]. The shaded band represents the opening rates computed from the pole of Minster and Jordan[7] at 80.43° N–56.36° W (angular rotation rate 0.258° Myr^{-1}) and includes the effect of the oval of confidence in pole position computed by these authors.

The difference between the two directions is always <10° and thus the correction factor never exceeds 0.984. The pattern of observed rates falls into the permissible band only when the averaging is conducted over a time interval of ~2.6 Myr. This is also true, although less so, when the data are averaged over 1.78 Myr. It is apparent from Fig. 2*a* that there is a departure from Minster and Jordan's model or any other rigid plate model when observed opening rates are averaged over the relatively short Brunhes time interval. The profile that yields the largest departure, at 29°36' N, corresponds to a misfit of 3.7 km in the position of the Brunhes reversal. This cannot be accounted for by the uncertainty in the model. To test the influence of the time scale which we have used we recomputed the opening rates (Fig. 2*b*) with the time scale of Mankinen and Dalrymple[18]. Although the discrepancy between observed and model rates is reduced, the data are clearly not compatible with rigid plate behaviour. In particular the opening rate observed at 29°36' N for the Brunhes epoch is greater than that observed at 21°06' N for the same time interval irrespective of the time scales. There is also evidence, in the region around 35° N where several data points are closely spaced, for strong departures from rigid plate behaviour even for a 2.6 Myr averaging interval. We will not emphasize this result, however, in the absence of a detailed survey, because the differences in opening rates are of the same order as the uncertainties in the determination of rates. The fact that, when averaging is done over about 2.6 Myr, the observed rates fall in the slower portion of Minster and Jordan's band may be evidence that the angular velocity for the North America–Africa motion computed by Minster and Jordan is too high.

We note in Fig. 2 the differences in opening rate north and south of 30° N. One may be tempted to locate a plate boundary at this latitude but it finds no support in the geology. We also note in Fig. 2 that the opening rates during the Brunhes epoch are systematically greater than the rates averaged over longer time intervals. To examine in more detail the opening rate variations as a function of time, we present in Fig. 3 the spreading rates for the east and west limbs of the ridge for the Brunhes epoch (0–0.69 Myr BP), the latter part of the Matuyama epoch (0.69–1.78 Myr BP) and the period before the Gilsa event (before 1.87 Myr). To compute a spreading rate for the Brunhes epoch we assume that the location of maximum depth of the rift valley within the inner floor[15] is the locus of accretion coinciding with zero age. Bathymetric information from Seabeam is very convenient for this purpose. The spreading rates for the other two time periods are derived directly from the models in Fig. 1. Two observations are apparent. First the distribution of spreading rates is approximately symmetric

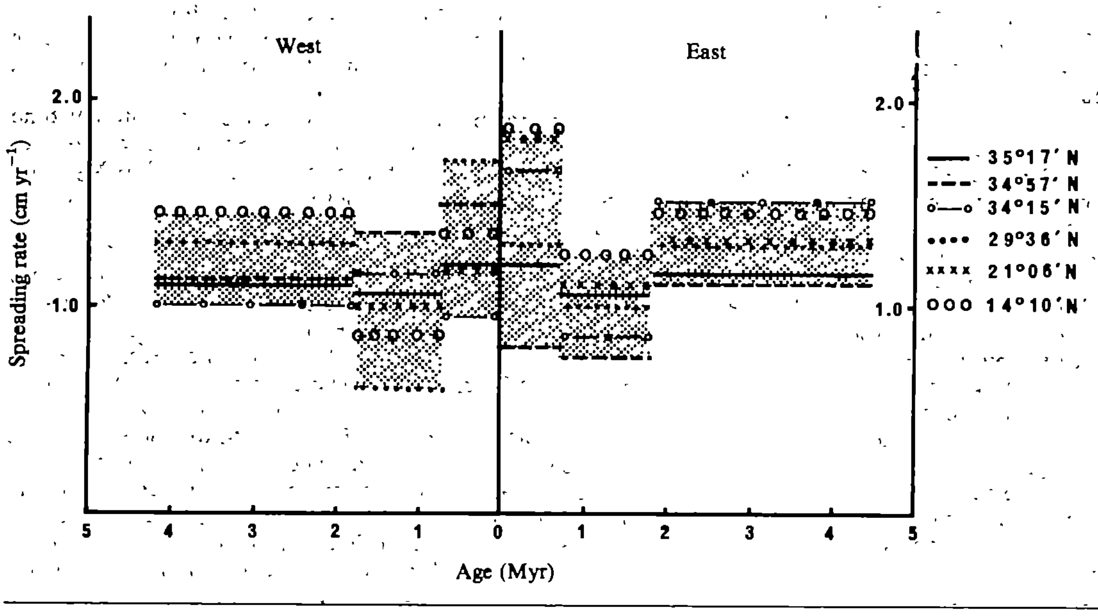

Fig. 3 Variation of spreading rates as a function of time. The spreading rates are keyed to their respective profiles. They are calculated for three time intervals: 0–0.69 Myr (Brunhes; anomaly 1), 0.69–1.78 Myr (Brunhes–Matuyama boundary to middle of anomaly 2), before 1.78 Myr.

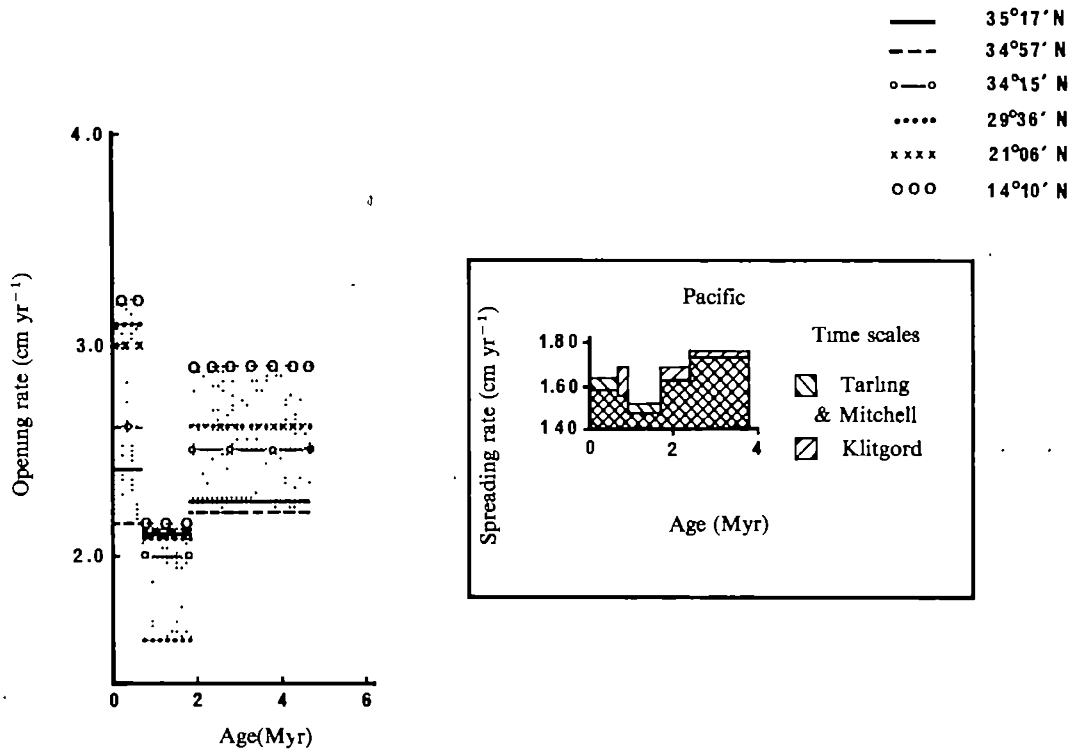

Fig. 4 Variation of opening rates as a function of time (derived from Fig. 3). Inset: variation of opening rates along the East Pacific Rise and Juan de Fuca Ridge (after Rea and Scheidegger[19]).

about the ridge axis—no one side is accreting crust systematically faster than the other side. Second, the Brunhes epoch is characterized by a distinctly faster rate of spreading compared with time intervals up to 4.6 Myr. Similarly the latter part of the Matuyama epoch from 0.69 to 1.78 Myr BP is characterized by smaller spreading rates.

One can ignore the distinction between east and west accretion because of the approximate symmetry about zero age in Fig. 3 and examine the variation of total opening rates as a function of crustal age (Fig. 4). There is a definite decrease in accretion rates for the 0.69–1.78 Myr BP period. The decrease is correlated with a change in spreading direction (H. Schouten, personal communication) particularly near the Kane fracture zone at 24° N. Rea and Scheidegger[19] also observed a definite slowing-down in plate accretion at the axis of the Juan de Fuca ridge (Fig. 4) which they linked to intraplate volcanism (Hawaii) and the dynamics of subduction[19]. We bring here some evidence that the spreading rate variations may be of global significance.

When accretion of the Mid-Atlantic Ridge is examined over a short time interval (<2 Myr) there is evidence that the oceanic plates do not behave rigidly. If we average the opening over a longer time interval (~2.6 Myr) the pattern of opening along the accreting plate boundary fits with that predicted by rigid plate behaviour. The evidence that we presented is derived from a rather simple modelling of magnetic anomalies but it is corroborated by more advanced modelling techniques[13]. The results are very sensitive to the position of the magnetic reversals but are not dependent on the number of sample points used in the 14–35° N interval. Thus, although we have used only a very limited data set, the departure from a rigid plate model is considered significant if one accepts the model results of Fig. 1. The modelling is strengthened by the fact that we have used magnetic profiles on two-dimensional bathymetry. The non-rigid opening between plates over short time intervals is not surprising and is consistent with the episodicity at the axis of mid-ocean ridges required by volcanic and tectonic data[20–22], geochronology[23,24], geochemistry and petrology (C. J. Allegre, personal communication) and hydrothermal activity (ref. 25 and R. D. Ballard, personal communication). It is clear that different segments of the Mid-Atlantic Ridge display an independent behaviour and, with respect to relatively short time intervals, may show departure from characteristics typically associated with slow accretion. This may provide a mechanism for initiating small transform faults. The size of each independent segment is not known, however, nor is known the behaviour of the ridge accretionary process over shorter time intervals for want of additional magnetic markers in the Brunhes epoch. One will probably need high resolution biostratigraphy for this purpose.

There is also evidence that the fluctuations of spreading rate with time may be global in nature although a close look is needed at other parts of the Atlantic and Pacific oceans and also in the Indian Ocean.

This is COB contribution no. 772.

Ultrathin mycelia-forming organisms from submarine volcanic areas having an optimum growth temperature of 105 °C

Karl O. Stetter

Lehrstuhl für Mikrobiologie, Universität Regensburg,
Universitätsstraße 31, D-8400 Regensburg, FRG

The most extremely thermophilic organisms known to date have been isolated from continental volcanic areas[1–3], and grow optimally between 70 and 85 °C. In the hope of finding organisms living at temperatures above 100 °C I have taken samples from the hot sea floor of a submarine solfatara field where, as a result of the high pressures liquid water is found that is hotter than 100 °C. Here I report that, from these samples, I isolated unusual disk-shaped prokaryotic organisms, connected by a network of thin hyphae, which grew at 100 °C in the presence of sulphur, hydrogen and carbon dioxide. The organisms could be successfully transferred to synthetic media and were strict anaerobes, growing optimally at 105 °C and not at all at 80 °C or below. However, they did survive for long periods at 4 °C and −20 °C in the absence of oxygen. During growth, H_2S was formed by sulphur reduction. Due to their extreme oxygen sensitivity, their unusual, irregular shape and primitive volcano-adapted metabolism, the novel organisms may represent a very ancient form of life existing in submarine volcanic areas in a water-supplied oxygen-free habitat, which has not changed for billions of years and which prevents competition with normal life due to prohibitively hot temperatures.

Extremely thermophilic organisms from submarine volcanic habitats have not been isolated previously. It has been assumed[4] that due to their high salinity, hot marine waters may contain less caldoactive organisms than the hot fresh waters occurring on the continent. Samples were collected from a submarine solfataric field close to the bay of Porto Levante, Vulcano Island, Italy. The sea floor was situated at a depth between 2 and 10 m and consisted mainly of sandy sediments with many small craters, and rock formations with gas-spewing, sulphur-encrusted holes and cracks. Temperatures of up to 103 °C were measured in the sediments and in the cracks and holes. Rubber gloves were used during sample collection to provide protection from the heat. The sediment was stirred as heavily and deeply as possible and material was then drawn into a syringe fitted with an enlarged inlet. The samples, still hot, were taken to the surface and transferred to storage bottles, which were immediately sealed with rubber stoppers, and then traces of oxygen were removed by injecting sodium dithionite[5]. Microscopic inspection of the samples revealed a small number of unusually flat organisms.

In the laboratory, sterile seawater was inoculated with the samples (5% inoculation) and incubated at 100 °C in the presence of sulphur and an H_2/CO_2 atmosphere (80:20 v/v; 2 bar pressure) with strict exclusion of oxygen[6]. Of the 21 samples taken from the sandy sediments and cracks, four yielded disk-shaped organisms which grew within 2 days. The original temperatures of the samples were all ~100 °C. The enrichment cultures were transferred successfully to a medium consisting of synthetic seawater supplemented with trace minerals[6], KH_2PO_4 (0.5 g l^{-1}), and sulphur (15 g l^{-1}). Growth occurred only in the presence of H_2 and CO_2. H_2S, which was formed as an end product, was identified as cadmium sulphide. During growth, the sulphur flowers became greyish and appeared corroded. After 1 week, the sulphur supply was depleted. Uninoculated controls neither showed this phenomenon nor produced H_2S. These observations indicate that the novel organisms acquire their energy by a sulphur–hydrogen autotrophy similar to that recently described for a rod-shaped bacterium from Iceland (ref. 7 and F. Fischer, W. Zillig and K. O. Stetter, in preparation).

The enrichment cultures were purified by serial dilution. During exponential growth (Fig. 1*a*,*b*), the pure cultures exhibited a doubling time of 550 min at 85 °C and of only 220 min at 100 °C (Fig. 1*b*). Surprisingly, the isolates grew optimally at 105 °C with a doubling time of 110 min (Fig. 1*b*). The isolates were transferred (1% inoculation) to fresh medium five times in succession and incubated at 105 °C. Microscopic inspection showed about the same high cell density in the last tube as in the first, indicating that the organisms multiplied at this temperature. At 110 °C, very weak growth occurred (not shown). It remains unclear whether this represents the upper temperature boundary, or whether, more probably, the reduction of growth was due to the sintering of the sulphur forming a lump and therefore rendering it inaccessible to the organisms. Below 80 °C, the isolates were unable to grow (not shown). However, they could be re-isolated from the original anaerobic samples, stored at 4 °C and at −20 °C over a period of at least 10 months. In the presence of oxygen, however, they were inactivated within hours.

Under the light microscope, the organisms appeared as flat disks, highly variable in diameter (from 0.3 to 2.5 μm), some having an indented, dish-like appearance. They were usually arranged in single file or in other formations with constant distances between each other. Under the electron microscope, most of the disks appeared to be connected by ultrathin rods up to 40 μm long (which are possibly hyphae; Fig. 2*a*) and only

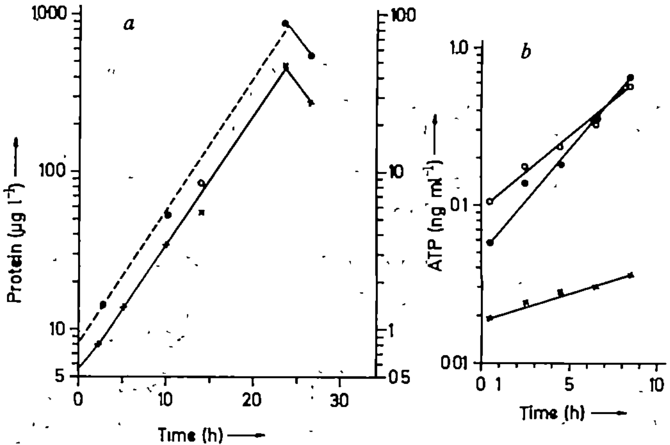

Fig. 1 Growth curves of the isolate PL-19. *a*, Growth in a 10-l fermenter at 95 °C: (×) ATP concentration; (•) protein concentration. The fermenter contained artificial seawater supplemented with 100 ml mineral mix[7], 5 g KH_2PO_4, 150 g flowers of sulphur, 10 mg resazurin and 5 g Na_2S, *p*H 5.5 (H_2SO_4). It was gassed with a mixture of H_2/CO_2 (80:20 v/v, 6 l h^{-1}). Stirring was at 50 r.p.m. For protein determination, 850-ml portions were centrifuged (8,000 r.p.m., 30 min; WKF G 50 K centrifuge). The pellets were solubilized in 200 μl SDS (2% w/v) and boiled for 5 min. From this solution, protein was determined as described elsewhere[9]. For ATP determination, 1 ml of culture was centrifuged at 21,000 r.p.m. for 2 min in a J 21 Beckman centrifuge. The pellet was solubilized in 30 μl NRB solution (Lumac); 10 μl of this solution were mixed with 100 μl Lumit buffer (Lumac), 90 μl twice-distilled H_2O and finally with 100 μl enzyme (Lumit PM; Lumac). Then, the sample was immediately analysed with a scintillation counter (Biocounter M 2010; Lumac). As a reference, 1 ng ATP yielded 10,958 counts in the same conditions. For medium without inoculation, the background was only ~20 counts. The doubling time, determined by protein and ATP amplification, was 220 min. *b*, Growth in closed 25-ml serum tubes at various temperatures: (×) 85 °C; (○) 100 °C; (•) 105 °C. The tubes contained 10 ml culture medium as described above and were pressurized (2 bars) with H_2/CO_2 (80:20 v/v). The tubes were each inoculated with 0.5 ml of an overnight culture grown at the same temperature. Samples (1 ml) were withdrawn using a syringe and ATP determined as described above. The doubling times were 550, 220 and 110 min at 85 °C, 100 °C and 105 °C, respectively.

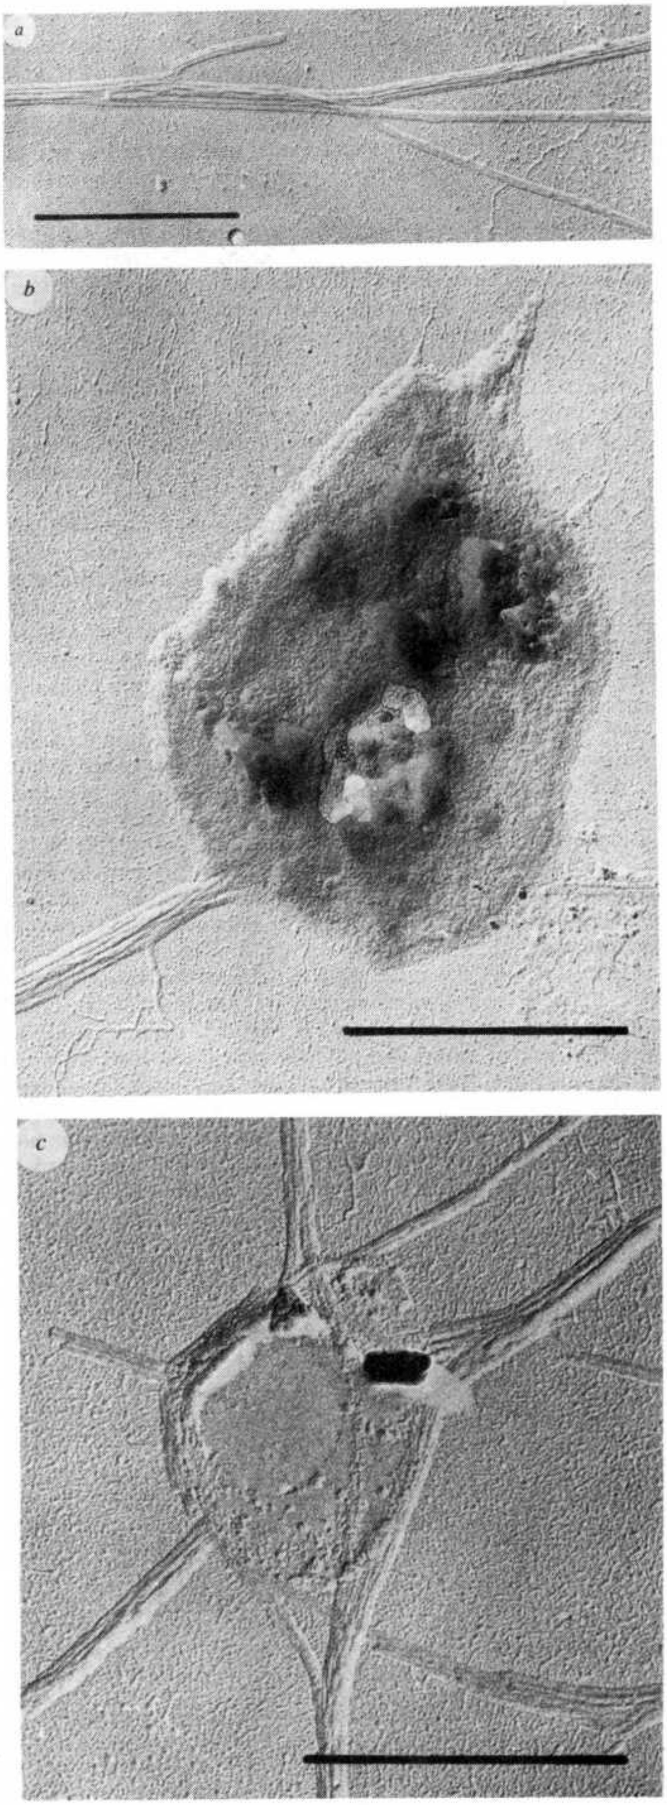

Fig. 2 Electron micrograph of isolate PL-19, platinum-shadowed. Scale bars, 1 µm. *a*, Bundle of hyphae; *b*, large disk-shaped cell situated laterally on a hypha; *c*, disk-shaped cell surrounded by hyphae.

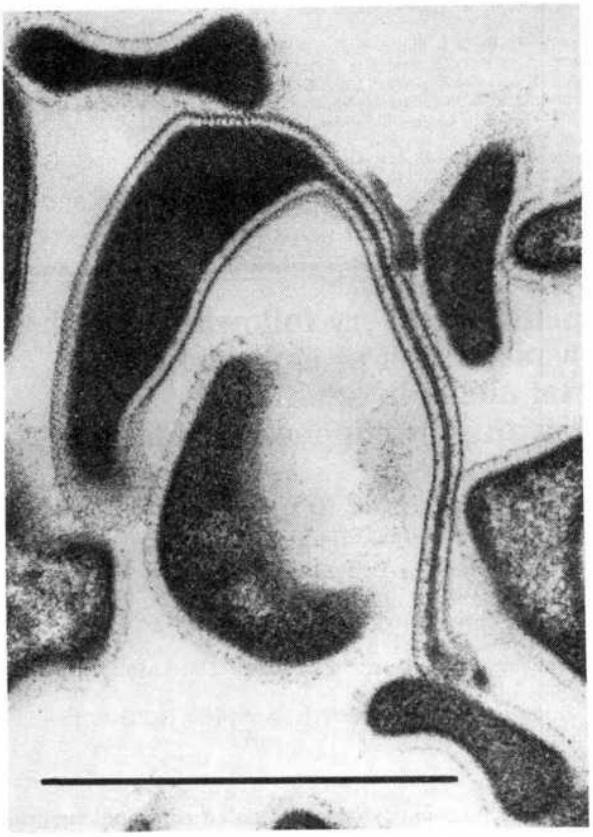

Fig. 3 Electron micrograph of thin sections of isolate PL-19. The sections were doubly contrasted with lead citrate and uranyl acetate. In the centre, a longitudinal section through a hypha attached to a disk-shaped cell is visible. Scale bar, 1 µm.

0.05–0.06 µm in diameter, thus they were not visible under the light microscope. The hyphae were often associated in bundles (Fig. 2*a*) or dispersed in loose networks covering areas of up to 10,000 μm^2. The disks were situated laterally (Fig. 2*b*) and terminally on the hyphae. Sometimes, disks appeared to be embraced by several hyphae (Fig. 2*c*). Thin sections revealed that both the disks and the hyphae were surrounded by a membrane and a protein envelope consisting of subunits ~30 nm in diameter (Fig. 3). The hyphae terminated within the disks without septa (Fig. 3); they formed only when the culture was grown without movement. Gentle stirring (200 r.p.m.) led to the formation of disks having no hyphae, and vigorous stirring (800 r.p.m.) led to rapid inactivation of the culture. Both the hyphae and the disks contained thin pili-like appendices (Fig. 2*a*,*b*) up to 5 µm long and 10 nm in diameter; occasionally these were branched, often cross-linking two individuals.

The taxonomic position of the novel organism described here is unclear. Preliminary studies of the membrane lipids (T. Langworthy, personal communication) and the existence of an ADP-ribosylable protein in the crude extract (F. Klink, personal communication) suggest that it may be a novel archaebacterium. As it is able to survive for long periods at low temperatures and due to its dependence on volcanic exhalations, this organism may be widely distributed in submarine volcanic areas.

After completion of this manuscript, Baross *et al.*[8] described the existence of bacterial communities in hot deep sea waters, which can grow at 100 °C in the laboratory and produce H_2, CH_4, CO and N_2O. The media used, however, contained no sulphur and neither H_2S formation nor growth at 105 °C was observed. Therefore, these organisms are very different from those reported here.

I thank Angelika Rechenmacher for technical assistance; Dr Helmut König and Elisabeth Kleemeier for electron microscopy; and Dr Heidi Stetter for assistance with sample collection. The laboratory work was supported by a grant from the Deutsche Forschungsgemeinschaft.

Function recovery following neural transplantation of embryonic septal nuclei in adult rats with septohippocampal lesions

Walter C. Low*§, Peter R. Lewis*, S. Terri Bunch*, Stephen B. Dunnett†, Stephen R. Thomas†, Susan D. Iversen†, Anders Björklund‡ & Ulf Stenevi‡

The remarkable capacity of transplanted embryonic neurones to innervate the hippocampal formation of mature recipients has been well documented, with the pattern of innervation being shown to be anatomically specific and to resemble normal connectivity[1–3]. Although transplants are known to have functional consequences in other systems[4–9], information has yet to be obtained regarding the functional nature of embryonic septal transplants and the behavioural consequences of transplant innervation of the host hippocampal formation. We provide here evidence that a reinnervation of the hippocampal formation from cholinergic-rich septal transplants is functional in terms of the physiology of neural connectivity and that the newly formed connections can interact with an intrinsic afferent system, the perforant path. Moreover, we demonstrate that the reinnervation can aid in the partial recovery of the performance of a radial maze task that is thought to depend on the integrity of septohippocampal connections[10]. The behavioural performance of animals with transplants improved significantly compared with those without transplants when both groups were systemically injected with the acetylcholinesterase (AChE) inhibitor, physostigmine. These results suggest that neural transplants from embryonic tissue that reinnervate the hippocampal formation can form functional synaptic connections that can lead to the partial restoration of maze performance.

Each of three groups of female Sprague–Dawley rats (~180 g) received either bilateral lesions of the fimbria–fornix transecting all septohippocampal and commissural fibres followed by bilateral septal transplants (transplant group, $n = 8$), or similar bilateral lesions of the fimbria–fornix without transplants (lesion group, $n = 7$), or sham operations (control group, $n = 7$). The transplanted septal–diagonal band area was taken from 16–17-day-old embryos (crown–rump length 15–20 mm) of the same strain and implanted into the cavity created by the suction lesion of the fimbria–fornix. The cavity exposed a vascular bed overlying the anterior thalamus, upon which the embryonic tissue was placed as previously described[11]. To permit the transplant to reinnervate the hippocampal formation, the animals were allowed to survive for 7 months before behavioural testing.

The rats were tested with a raised eight-arm radial maze, as Olton *et al.*[10] have shown that the performance of this task is disrupted by damage to septohippocampal afferents. Rats were stabilized on a 23-h food deprivation schedule, which was maintained throughout behavioural testing. During each daily trial, each arm of the maze was baited and the rat was placed in the central arena, free to enter any arm in any order. Once the animal had entered an arm and consumed the pellet it received no food on subsequent visits to that arm. Optimal performance by the rat involved choosing only arms that had not previously been visited. The performance of each animal was determined by the number of correct arms (those arms that it had not previously visited during the trial) selected out of the first eight choices.

Analysis of maze performance during the first 30 days of testing revealed that the three groups differed significantly ($F = 4.93$ with 2, 19 d.f.). The control animals showed a gradual improvement over the first 15 days of testing and stabilized thereafter (linear trend over 30 days, $F = 12.64$ with 1, 54 d.f., $P < 0.001$). The performance of animals with bilateral lesions did not improve with repeated trials (analysis of linear trend not significant, $F = 0.02$ with 1, 54 d.f.). The animals with septal transplants, however, did improve over the 30 days of testing (linear trend $F = 4.26$ with 1, 63 d.f., $P < 0.05$), but their overall improvement was not as great as that of the control group and their overall performance did not differ significantly from the bilaterally lesioned animals.

We postulated that the lack of overall improvement in the transplant group when compared with the lesion group might be due to insufficient cholinergic innervation. To test this hypothesis, all animals were tested for an additional 8 days during which they were alternately injected (intraperitonally, i.p.) with 0.05 mg per kg of physostigmine, an acetylcholinesterase inhibitor, or with an equal volume of saline. Physostigmine has previously been shown to enhance discrimination performance[12,13].

Figure 1 shows the maze performance of the three groups under saline and physostigmine; the interaction between groups and drug was significant ($F = 4.13$ with 2, 18 d.f., $P < 0.05$). Both the control group and animals with transplants showed enhanced maze performance under the drug (planned orthogonal comparisons, $P < 0.005$ and $P < 0.001$, respectively) whereas the bilaterally lesioned group showed no improvement ($P > 0.25$). These results indicate that embryonic septal transplants can aid in the partial restoration of maze performance.

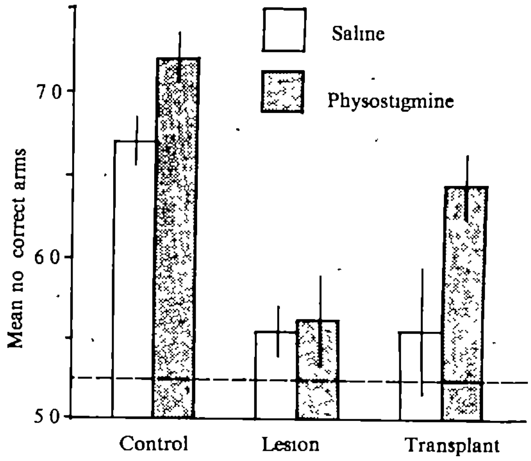

Fig. 1 Mean maze performance of rats with control sham operations ($n = 7$), fimbria–fornix lesions ($n = 7$) and septal transplants ($n = 8$) following injections of isotonic saline or 0.05 mg per kg physostigmine; vertical bars represent s.e.m. Both the control and transplant groups, but not the lesion group, showed significantly improved performance following injection of the cholinesterase inhibitor ($P < 0.05$, $P < 0.001$, and $P > 0.25$, respectively). The horizontal dashed line in each graph represents the random performance level.

In particular, the enhanced maze performance with physostigmine administration in the transplant and control group, but not the lesion group, indicates that recovery is dependent on the re-formed cholinergic connections.

In addition to the extent of the cholinergic reinnervation, the complexity of the eight-arm maze task might affect the performance of the transplant and lesion groups. Roberts and Dale[14] have shown that rats tested with such a radial maze begin to adopt strategies when the memory requirements are quite demanding. Although animals of both groups tended to adopt strategies, the strategy generally adopted was to select alternate arms. This proved to be an unsuccessful strategy in that after the first four correct choices, rats would then enter arms that had been visited previously. Consequently, if an animal persisted in this strategy, it would err in its next four choices. Interestingly, animals in our control group did not have a tendency to adopt strategies, even successful strategies such as selecting adjacent arms as reported by Roberts and Dale[14]. When tested in maze tasks with less complexity, animals with transplants have been shown to perform significantly better than bilaterally lesioned animals without the aid of physostigmine[15].

On completion of the behavioural trials, five animals with septal transplants and one animal with fimbria–fornix lesion alone were used for electrophysiological analysis. The region of the dentate gyrus within the hippocampal formation was analysed because of the dense reinnervation in this area by the transplant as revealed by preliminary histological studies using AChE histochemistry. Furthermore, perforant path fibres from the entorhinal cortex also project to the granule cells of the dentate, and when electrically stimulated, evoke characteristic field potentials in the dendritic and somatic zones of the granule cell layer[16,17] (Fig. 2*a*, left panel).

The rats were anaesthetized with urethane (1.5 g per kg, i.p.) and placed in a stereotaxic apparatus where the transplant and surrounding neocortex were exposed and kept under saline. A field potential recording electrode was placed within the granule cell region of the dentate gyrus (anterior −3.5 mm, lateral 2.5 mm, vertical −2.7 to −3.7 mm with respect to bregma, incisor bar at −4.0 mm), and stimulating electrodes were placed on the transplant and in the angular bundle of the perforant path (anterior −8.1 mm, lateral −2.0 mm, vertical −2.0 to −3.0 mm). In all five animals studied with septal transplants, stimulation of the transplant resulted in positive-going monophasic field potential responses in the granule cell layer of the dentate (Fig. 2*a*, right panel, depth at 0 μm). The stimulation of the tissue surrounding the cavity in the lesioned animal without a transplant did not evoke field potential responses in the dentate.

Depth profile analysis of field potentials provided further evidence for the functional nature of the transplant innervation of the host. The depth profile (Fig. 2*a*) shows the field potentials evoked by alternating perforant path (left panel) and transplant stimulation (right panel) at successive depths during a single electrode penetration through the laminae of the dentate gyrus. The perforant path-evoked synaptic wave in the dentate exhibited a sharp polarity reversal as the electrode was moved from the dendritic zone down into the cell body layer. This characteristic reversal of the perforant path-evoked synaptic field potential in the dentate reflects the pattern of monosynaptic innervation from the perforant path which is confined to the mid and outer regions of the granule cell dendritic layer[18,19]. The transplant-evoked response during the same traverse continued to exhibit positive-going field potentials. Superimposed on these potentials were negative deflections which were observed when the recording electrode was situated in the dendritic region.

The innervation arising from the transplant was examined further to test its ability to interact with the fibre innervation arising from the perforant path. In this set of experiments, we set the stimulus intensity for the activation of perforant path fibres at a level that was insufficient to evoke the synchronous discharge of granule cells or population spike (Fig. 2*b*, trace 1). When the stimulation of the perforant path was preceded by the stimulation of the transplant, a prominent perforant path evoked population spike was observed (Fig. 2*b*, trace 2) which was maximal with inter-stimulus intervals in the range of 30–70 ms.

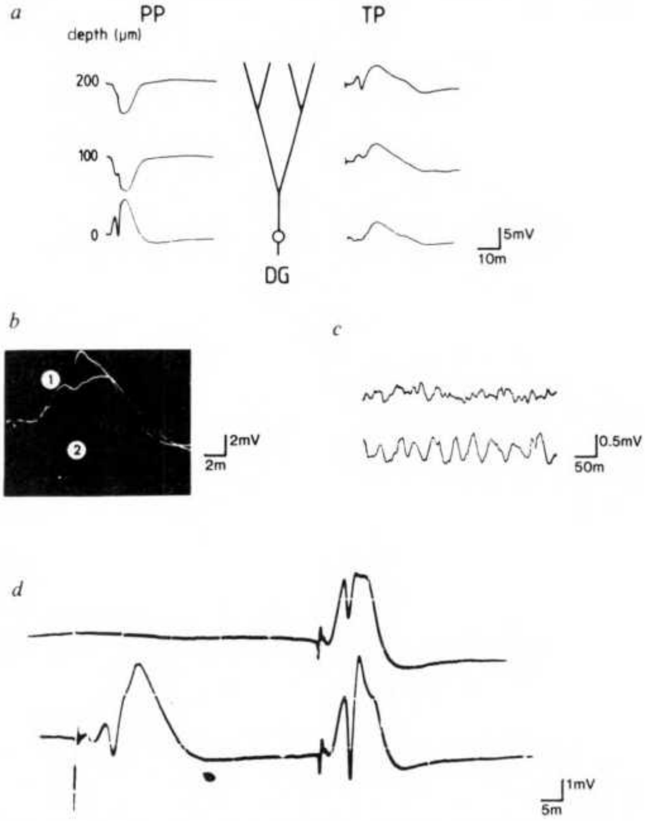

Fig. 2 Electrophysiology of dentate innervation. *a*, Vertical field potential profile of perforant path (PP) and transplant (TP) evoked responses through dentate laminae. Recording electrode positions relative to granule cell body layer (DG) are indicated. *b*, Subthreshold PP–dentate-evoked response (trace 1) and potentiated PP–dentate-evoked response (trace 2) potentiated by TP stimulation preceding PP stimulation by 50 ms. *c*, Monopolar recording of slow-wave activity (filters 0.1–100 Hz) from theta-generating zone of the dentate molecular layer 15 min after injection of physostigmine (0.05 mg per kg). Slow-wave activity in the theta-frequency range (6–10 Hz) is absent. An irregular pattern predominates (upper trace), interspersed with periods of regular sinusoidal activity at higher frequencies (15–20 Hz, lower trace). *d*, Field potentials from animal with intact septohippocampal connections. Trace 1: submaximal PP–dentate-evoked response. Trace 2: septo-dentate-evoked response (left) followed by potentiated PP–dentate-evoked response (right). All traces shown are positive up in polarity and calibrated individually.

Similar evoked responses and heterosynaptic interactions were observed in control animals with intact septohippocamporal connections. Stimulating electrodes were placed in the dorsal aspect of the medial septum and the angular bundle of the perforant path in rats anaesthetized with urethane (1.5 g per kg, i.p.). A recording electrode was placed in the granule cell layer of the dentate. Electrical stimulation of the perforant path alone evoked a population spike response as shown in trace 1 of Fig. 2*d*. When the stimulation of the perforant path was preceded by the stimulation of the dorsal aspect of the medial septum (50 ms interstimulus interval) the perforant path–dentate-evoked response was markedly potentiated (Fig. 2*d*, trace 2). The first response shown on trace 2 of Fig. 2 is the positive-going dentate field potential resulting from the stimulation of the medial septum. Superimposed on this is a negative deflection probably due to the synchronous activation of granule cells. The second response of trace 2 is the potentiated perforant path–dentate population spike. Septo-dentate-evoked responses have been demonstrated by other investigators[20], as well as heterosynaptic interactions within the hippocampal formation[21,22]. Note that in contrast to the presence of the negative-going septo-dentate spike as recorded in the granule cell layer of control animals, animals with septal transplants did not exhibit such spikes when the transplant was stimulated. The absence of the negative spike in these animals may be due to an insufficient convergence of fibres from the transplant required to synchronously activate the granule cells.

In the final set of electrophysiological experiments with the transplant group, we attempted to induce low-frequency (6–10 Hz) rhythmical electrical activity in the hippocampal formation (theta waves), which is thought to be paced by the medial septum[23,24]. Injections of physostigmine (0.05 mg per kg, i.p.) were capable of inducing rhythmical activity, but at frequencies higher than theta activity (Fig. 2*c*). The lack of theta activity may reflect an insufficient cholinergic reinnervation and/or the absence of other non-cholinergic afferents which were eliminated during the lesioning procedure. This, in turn, may account for the incomplete restoration of maze behaviour.

After the behavioural and electrophysiological studies animals were processed for AChE histochemistry. The animals with septal transplants, but not those with lesions alone, exhibited AChE-positive staining in the dorsal hippocampus with a laminar distribution typical of the cholinergic innervation in intact animals, as has been described in detail elsewhere[3].

Thus, the present study provides evidence that septal transplants are capable of forming physiologically viable connections with the hippocampal formation of the recipient. These connections, in turn, can enhance the efficacy of the perforant path input to the dentate gyrus. The cholinergic reinnervation, moreover, seems to account for the partial recovery of performance as examined with an eight-arm radial maze. The behavioural manifestations of the transplants, however, must also be viewed in the light of investigations demonstrating the ability of intracerebral transplants to become innervated by the host tissue[25–27]. Heterosynaptic interactions and interconnections indicate that the host and transplant are capable of integration in a physiological and anatomical sense. Such an integration provides a framework for the processing of neural information mediating the partial recovery of behavioural responses.

Effector T lymphocyte line cells migrate to the thymus and persist there

The thymus gland has been known for some time to be the central organ of differentiation of T lymphocytes[1,2]. Stem cells migrate into the thymus from the bone marrow, differentiate and, as competent T lymphocytes, disperse from the thymus to the periphery, where contact with specific antigen induces immune reactivity[2]. The traffic of T lymphocytes between the thymus and periphery has been thought to be unidirectional and, unless the cells are leukaemic[3] or the thymus gland has been irradiated[4], re-entry of peripheral T lymphocytes has not been detected[3]. We now report that cells from lines of functionally active T lymphocytes reactive to self or foreign antigens can migrate back into the normal thymus gland and persist there for relatively long periods in a quiescent state until activated by contact with antigen. Hence, in addition to being the seat of T lymphocyte differentiation, the thymus is open to two-way traffic with the periphery and may function as a repository of immunological memory.

The experiments described here were prompted by our investigation of the behaviour of cells of functional T lymphocyte lines. We have found that lines of rat T lymphocytes specific for the basic protein of myelin could cause experimental autoimmune encephalomyelitis (EAE) upon intravenous inoculation into naive recipient rats[5,6]. Moreover, cells from such lines, attenuated by treatment with mitomycin C or irradiation, could be used for vaccinating rats against the induction of active EAE by subsequent immunization of the rats to myelin basic protein[7,8]. To study the migrations of such cells, we labelled them with radioactive chromium-51, injected them into rats intravenously and measured the accumulation of radioactivity as an indication of the accumulation of the injected cells in various organs. We found that anti-myelin basic protein cells accumulated in the brain and spinal cord about one day before the onset of EAE (Fig. 1). Cells from lines reactive to other antigens, such as tuberculin (PPD), did not accumulate in the central nervous system. However, Fig. 1 shows that about 1% of injected anti-myelin basic protein or anti-PPD line cells accumulated in the thymus glands of recipient rats beginning 3 days after intravenous inoculation. Accumulation in the thymus was detectable only if the cells were intact and had been activated by incubation with specific antigen before inoculation. Non-activated cells did not enter the thymus, nor did activated and irradiated cells. It is noteworthy that nonactivated, or activated and irradiated cells also did not mediate EAE[7] or transfer delayed hypersensitivity (manuscript in preparation). Thus, migration to the thymus appeared to be correlated with the state of the T lymphocytes and their capacity to mediate specific immunological effects.

Experiments were then designed to answer three questions: (1) do the returned T lymphocytes persist in the thymus, (2) are they capable of responding to specific antigen and (3) do they include potential effector cells? We injected female anti-myelin basic protein or anti-PPD line cells into syngeneic male recipient rats, and two months later we assayed the proliferative responses of their thymus cells to myelin basic protein or PPD.

0028–0836/82/460262—03$01.00

The thymus glands used in the experiments were dissected free of the lymph nodes imbedded in their postero-lateral portions. The results are shown in Table 1. Control thymus cells from naive rats showed no response to myelin basic protein and only a weak response to PPD (SI = 2). The thymus cells of rats that had been inoculated intravenously with activated anti-myelin basic protein line cells and had recovered from EAE[8,11] responded weakly to myelin basic protein (SI = 3). The slight response to PPD of these thymus cells was about the same as that of naive control rats (SI = 2). Injection of anti-myelin basic protein cells did not produce a response to PPD. In contrast, thymus cells from rats that had been inoculated with activated anti-PPD cells showed a response to PPD (SI = 6) but not to myelin basic protein. Nonactivated anti-PPD cells produced no response.

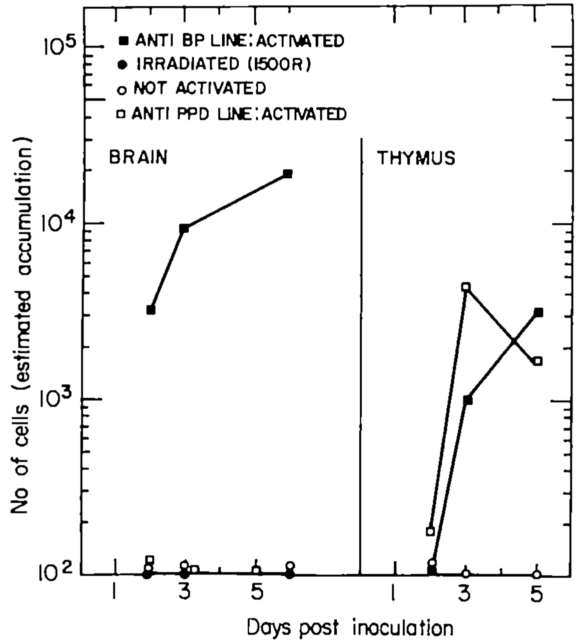

Fig. 1 Activated anti-myelin basic protein cells accumulate in the brain and thymus; activated anti-PPD line cells accumulate in the thymus. Lines of T lymphocytes specifically responsive to myelin basic protein or to PPD were raised from lymph node cells of 3-month old female Fischer rats that had been immunized with myelin basic protein-CFA[5,6]. The cells were maintained in medium containing T cell growth factor[9] and some of the cells were activated by incubation with their respective antigen, myelin basic protein or PPD in the presence of irradiated (1,500 rad) normal thymus accessory cells for 72 h (refs. 5, 6): some of these activated cells were irradiated with 1,500 rad. The line cells were labelled[10] by incubating 10^7 cells per ml Eagle's medium containing ^{51}Cr as sodium chromate (Amersham). The cells were washed by centrifugation in medium. Groups of 6 male Fischer rats were then inoculated into the tail vein with 3×10^6 labelled cells from lines of each type. On days 2, 3, 5 or 6, two rats of each group were killed and the accumulated line cells in the brains and thymuses were estimated by the c.p.m. emanating from each whole organ measured in a gamma counter. Differences between the organs of the two rats assayed at each time point were negligible. The number of cells was computed as the c.p.m. divided by the c.p.m. per cell in the inoculum. Similar results were obtained in four consecutive experiments.

To determine the immunospecificity of the cells responding to myelin basic protein and to determine their origin, they were grown in medium containing T-cell growth factor (IL-2)[9] with alternating periods of stimulation with myelin basic protein until they developed into a stable line of T lymphocytes[6]. Accessory cells added during stimulation with myelin basic protein were of male origin, as were the recipient rats from whom the thymuses were taken for culture. Thus, only the original line cells inoculated over 2 months earlier were of female origin.

Table 1 shows that cells recovered from anti-myelin basic protein lines responded strongly and specifically to the antigen *in vitro* (SI = 13), and mediated EAE upon intravenous inoculation into naive Fischer rats. Furthermore, analysis of the chromosomes of the recovered anti-myelin basic protein cells showed that they all had the female karyotype of the original line. Therefore, the antigen-specific cells detectable in the thymus 2 months after inoculation and spontaneous recovery from EAE were cells of the donor EAE effector line. Similar results were obtained in experiments using rats and line cells of the Lewis rat strain.

These findings indicate that competent, specifically sensitized T lymphocytes can re-enter the thymus and persist there. Thus, the thymus is connected to the periphery by a two-way flow of potential effector lymphocytes. The T lymphocytes that leave the thymus appear to be those induced to differentiate from precursors by contact with epithelial cells of the thymic stroma[13] or with macrophage-like cells[14]. This stage of differentiation is not dependent on clonal recognition of specific antigens but may involve the acquisition of the restriction of antigen recognition to association with particular products of the major histocompatibility complex[15,16]. In contrast, the T lymphocytes that return to the thymus from the periphery appear to be induced to do so in response to antigen. The cell lines used in these experiments were developed from cells of antigen-primed rats by their proliferative responses to specific antigens and by their ability to respond to T cell growth factor[5,6]. Furthermore, the cells did not return to the thymus and persist there unless

Table 1 Activated female anti-myelin basic protein T lymphocyte line cells persist in male thymus and can be recovered

Female line cells inoculated into male rats		Thymus cells		Recovered anti-myelin basic protein cells				
		Proliferation Δ c.p.m. (SI)		Proliferation Δ c.p.m. (SI)			Karyotype	
Specificity	Treatment	Myelin basic protein	PPD	Myelin basic protein	PPD	Incidence of EAE	Male	Female
None	None	95 (1)	921 (2)					
Anti-myelin basic protein	Activated	3,156 (3)	1,376 (2)	82,051 (13)	0 (1)	5/5	0/20	20/20
	Irradiated	0 (1)	880 (1)					
	Nonactivated	0 (1)	995 (2)					
Anti-PPD	Activated	0 (1)	4,984 (6)					
	Nonactivated	0 (1)	950 (2)					

Proliferative responses to myelin basic protein or to PPD of thymus cells from groups of five male 3-month old Fischer rats were measured[5,8]. Some of the groups had been inoculated i.v. 2 months earlier with 3×10^6 female anti-myelin basic protein or anti-PPD line cells[5,6]. Cells from the lines were either nonactivated, activated or activated and irradiated (see Fig. 1 legend). Rats that had been inoculated with anti-myelin basic protein line cells developed EAE 4 days later and recovered spontaneously[6,11]. An anti-myelin basic protein line was recovered from pooled thymuses free of lymphnodes of the male rats that had been inoculated with the female activated anti-myelin basic protein line cells[6]. The proliferative responses of these line cells to myelin basic protein and to PPD were tested[6], as was their ability to mediate EAE in naive recipient rats. The karyotype of the anti-myelin basic protein line cells was studied in 20 cells[12].

they had had contact with their specific antigen just before inoculation. Thus, the capacity of anti-myelin basic protein T lymphocytes to return to the thymus, to persist there and to mediate EAE appeared to be part of the programme of differentiation induced by the antigen. In their persistence and response to specific recall, these cells are a token of immunological memory.

We also have been able to recover EAE effector T lymphocytes from the thymuses of rats that had recovered from EAE induced by active immunization to BP in adjuvant[11]. Thus, the thymic immigration of effector T lymphocytes would seem to include cells generated endogenously as well as exogenous line cells. The anatomical site of residence in the thymus of the returned T lymphocytes is unknown, but it is probable that they comprise part of the pool of relatively mature longlived cells residing in the medulla[17].

The present observation raises a number of questions. Are all populations of sensitized lymphocytes represented in the thymus? Are some sensitized T lymphocytes specifically destined to return to the thymus because they bear particular receptors, or is the return a random process in which all sets of T lymphocytes participate equally? Does the persistence in the thymus of these returned cells have a role in immunological memory? Why and how are persistent autoimmune effector T lymphocytes kept quiescent? Is activation of such cells a factor in the progression or exacerbation of autoimmune diseases? Or, on the contrary, does the persistence of autoimmune cells help maintain self-tolerance by priming anti-idiotypic networks[18]?

Human hybridomas secreting anti-islet autoantibodies

G. S. Eisenbarth‡, A. Linnenbach†, R. Jackson*, R. Searce* & C. M. Croce†

* Joslin Research Laboratories, Department of Medicine, Brigham and Womens Hospital, Harvard Medical School, Boston, Massachusetts 02215, USA, and the Department of Medicine, Duke University Medical Center, Durham, North Carolina 27710, USA

Serum from patients with type I diabetes mellitus contains antibodies which react with all islet cells on sections of human pancreas[1], normal rat islet cell surface antigens[2], antigens expressed by islet cell tumours[3], β-cell-specific surface antigens[4] and A cells of sections of human pancreas[5]. Due in part to the low titre of anti-islet antibodies, the biochemistry of the relevant islet cell antigens is poorly understood[6]. Our laboratory has begun to develop and define a series of murine monoclonal anti-islet antibodies[7–9]. In addition, we have begun to explore the possibility of producing human hybridomas secreting monoclonal anti-islet antibodies by fusing lymphocytes from patients having type I diabetes mellitus with human myeloma cell lines. We describe here the isolation of human hybridomas that secrete human monoclonal anti-islet antibody. The availability of hybridoma clones secreting autoantibody should result in a better understanding of the mechanisms resulting in the expression of human autoantibodies.

After two unsuccessful fusions in which no anti-islet antibodies were detected, lymphocytes from 20 ml of blood from a patient with type I diabetes mellitus of 5 months' duration were fused using polyethylene glycol with the GM1500 6TG-2 myeloma-derived cell line (10^7 myeloma cells, $\sim 2\times 10^7$ lymphocytes)[10]. Using frozen sectioned pancreas and fluorescein-conjugated rabbit anti-IgG antibodies, the patient's serum reacted strongly with all islet cells in a typical anti-islet pattern, while with fluorescein-conjugated anti-IgM antibody it reacted selectively with peripheral islet cells, suggestive of an A-cell pattern[5]. After fusion, the resulting cells were distributed into 24 wells of a Linbro plate; colonies developed in 22 of the wells. Supernatants from these 22 hybrid cultures were tested for the presence of anti-islet antibodies reacting either with the cell surface of viable rat insulinoma cells or with islets of Bouin's fixed human pancreas. No supernatants contained an anti-cell-surface antibody.
